Abstract

Tubulointerstitial nephritis (TIN) is an immunologically mediated inflammation of renal tubulointerstitium with relative sparing of glomeruli and vessels. Clinical symptoms and laboratory findings of TIN are often unspecific, resulting in a delayed diagnosis, which may lead to a poorer clinical outcome. Renal biopsy is the gold standard of the diagnosis and shows an inflammatory interstitial infiltrate and interstitial edema. Drug-induced TIN accounts for most cases, with antibiotics, proton-pump inhibitors, and NSAIDs as leading etiologic agents. TIN can be diagnosed in association with infections, systemic disease, uveitis, and toxic factors. TIN can be acute and reversible if the offending factor is withdrawn, or may represent a chronic process leading to irreversible renal failure. The role of corticosteroids and other immunosuppressive agents in the treatment of acute TIN is controversial.

Introduction

Tubulointerstitial nephritis (TIN) is an immunologically mediated inflammation of the renal interstitium that can be the cause of acute kidney injury. Tubules and vessels are involved in the inflammatory process to a variable extent [1, 2]. Since around 85% of kidney tissue is made up of tubules and the surrounding interstitium, these structures are of crucial importance in renal disease processes [3]. Clinical symptoms and laboratory findings of tubulointerstitial nephritis are often unspecific, so that this can result in a delayed diagnosis and a poorer clinical outcome [4]. Renal biopsy is the gold standard of the diagnosis of tubulointerstitial nephritis and shows an inflammatory interstitial infiltrate and interstitial edema [5]. In rare cases, the interstitial inflammation leads to chronic renal impairment [6]. TIN is characterized histologically by inflammation and damage of tubulointerstitial structures, with relative sparing of glomerular and vascular elements. It can be acute or chronic in its appearance and course. The likelihood of chronicity increases with systemic inflammatory or rheumatologic diseases and delayed removal of the causative medication in drug-induced TIN. Biopsy proven drug-induced acute TIN accounts for most cases (71%), of which antibiotics represent the most common responsible class of drug followed by proton-pump inhibitors and NSAIDs [7]. In adult patients with AKI, AIN represents 18% to 27% of biopsied cases [8, 9, 10, 11].

In recent years, the prevalence of TIN seems to continue to increase, especially in patients over 65 years of age, most likely due to the widespread use of antibiotics, nonsteroidal anti-inflammatory drugs (NSAID), and proton pump inhibitors (PPIs), which are common triggers of TIN [6, 12]. With the exception of TINU syndrome (tubulointerstitial nephritis with uveitis, see below), the disease is significantly more common in adults than in children.

This chapter focuses on acute TIN.

Structure and Function of the Tubulointerstitial Compartment

The tubulointerstitial compartment consists of tubular epithelium, vascular structures, lymphatics, and interstitium, together accounting for more than 90% of the kidney volume [13]. The interstitium fills the space between tubular and vascular basement membranes. It is composed of extracellular matrix with matrix proteins, including collagen I, III, V, and VII, fibronectin, osteopontin, and proteoglycans, which are expressed normally in very small amounts, interstitial fluid, and a large number of intrinsic and infiltrating cells. It provides structural support for the nephrons and capillaries and plays an important role in the transport of solutes and production of cytokines and hormones such as prostaglandins and erythropoietin [11]. Separation into cortical and medullary interstitia allows countercurrent medullary solute trapping and the development of the corticomedullary osmotic gradient, establishing kidney concentrating ability [14].

Multiple cell types are important components of the interstitium. Perivascular cells (pericytes) reside between macula densa and afferent arterioles, participating in renal autoregulation. Fibroblasts constitute the major cell type in the interstitium. They determine matrix production and degradation and form a continuous network throughout the kidney [15]. Erythropoietin production occurs in the peritubular interstitial fibroblasts [16] stimulated by hypoxia through the activation of hypoxia-inducible transcription factors (HIF) [17].

Circulating monocytes migrate into the kidney and transform into renal interstitial macrophages, which can differentiate into inflammatory M1 or reparative M2 phenotypes [18]. Dendritic cells are bone-marrow derived antigen-presenting cells that express MHC class II [19]. They interact with T cells within the interstitial lymphatic network to process antigens and elicit inflammatory responses [20]. Following tubular damage and inflammatory signals interstitial fibroblasts proliferate, change to the myofibroblast phenotype, and increase their collagen production, potentially resulting in renal fibrosis [16]. Tubular epithelial cells have antigen-presenting capability, can secrete various growth factors and cytokines, interact with interstitium, and participate in interstitial inflammation in various pathologic conditions [21].

According to these multiple functions and properties of tubulointerstitial compartment, its damage leads to different metabolic disturbances, including impaired renal function and concentrating ability, anemia, and possible fibrosis development and progression to chronic kidney disease (CKD).

Pathophysiology of TIN

Pathogenesis

Tubulointerstitial nephritis is characterized by an inflammatory cell infiltrate, interstitial edema, and tubulitis. This process is often immune mediated, driven by activation of both innate and adaptive immune, or nonimmune responses. If prolonged, TIN leads to interstitial fibrosis as the final common pathway. The previously proposed leading mechanism by allergic hypersensitivity with systemic and tissue eosinophilia in drug-induced TIN is not universal, and different pathways in drug-induced conditions can be seen, as with nonsteroidal anti-inflammatory drugs (NSAIDs), where interstitial eosinophils infiltration lacks, implicating a non–type IV drug-hypersensitivity reaction [22]. However, the possible role of mast cell activation by IgE has been shown in a human study [23].

The composition of the interstitial infiltrate is similar, whether the initiating cause of injury is toxic, ischemic [24], autoimmune [25], or secondary to protein overload [26]. It is possible that immune responses to injured interstitial cell neoantigens are a final common pathway for interstitial injury.

Recent experimental studies have uncovered a new pathogenetic mechanism called "necroinflammation," defined as immune response to necrosis in living organism, which links primary tubular damage with an interstitial inflammatory response [27]. This mechanism was recently reviewed in the context of drug-induced interstitial nephritis [28]. "Necroinflammation" is triggered by a specific form of necrotic cell death (necroptosis) characterized by plasma membrane rupture and proinflammatory cytokine release, increased vascular permeability, and recruitment of innate immune effector cells. Initial renal damage leads to inflammation and cause additional tubular cell necroptosis, setting an injury amplification loop. If not arrested, it will eventually lead to organ dysfunction. Necrotic cell particles can form danger-associated molecular patterns (DAMPs) and activate specific pattern recognition receptors (PRR), including several Toll-like cellular membrane receptors and intracellular receptors. These receptors are expressed by immune or nonimmune cells, including many native kidney cells. This ligand-receptor interaction triggers the release of various pro-inflammatory mediators and cytokines leading to an inflammatory response [29].

Studies from experimental models of tubulointerstitial disease indicate that both cell-mediated and humoral immune mechanisms are relevant pathways for inducing renal injury [30].

Cell-mediated immune response to initial injury promotes interstitial inflammation and tubular injury via infiltration of lymphocytes, neutrophils, macrophages, mast cells, and eosinophils. Of these, T cells including $CD4^+$ and $CD8^+$ constitute 80% of the infiltrating cells [31]. Cell-mediated responses are initiated by T-cell recognition of antigens presented on antigen-presenting dendritic cells and renal tubular epithelial cells that express MHC molecules, as previously mentioned. Costimulatory molecules CD80 and CD86 are needed for this process [32]. Under physiologic conditions antigen-presenting ability of renal cells is limited, preventing inflammatory response. Genetic susceptibility may play a factor in antigen expression and consequent immune response [33], as well as drugs, infectious agents, or molecular mimicry that may serve as inciting antigens of cell-mediated responses targeting the kidney [34]. Monocytes and macrophages infiltrating the renal interstitium cause cellular damage by generating reactive oxygen species, nitric oxide, complement factors, and proinflammatory cytokines [35]. These cells can also affect supporting matrix and vasculature through the expression of metalloproteinases and vasoactive peptides. Proper macrophages function is important for the clearance of danger-associated molecular patterns (DAMPs), pathogen-associated molecular patterns, and neutrophils from injured tissue preventing persistent inflammation [36]. Interstitial macrophages have phenotypic and functional heterogeneity and may also have a beneficial antifibrotic role in inflammation [37].

Tubulointerstitial inflammation may develop also in the absence of antigenic stimulation [38]. There is growing evidence for the role of innate immune sensors (TLR2, TLR4, and MyD88 signaling) and the inflammasome complex in the initiation of tubulointerstitial injury [39]. In nonimmune-mediated TIN, ammonia can activate the alternative complement pathway [40], which indicates the importance of correction of metabolic acidosis in the prevention of progressive damage to the kidneys by diminishing ammonia production.

Antibody-mediated TIN is rarely seen. Immune deposits on renal biopsy can be seen along the tubular basement membrane (TBM) and represent specific anti-TBM antibodies or reflect immune complexes deposited in this area. Immune complexes in interstitial nephritis are probably formed in situ, similar to what has been shown in post-streptococcal glomerulonephritis [41]. The deposits generally consist of IgG and complement factor C3. However, TIN with IgM deposits has been described [42]. Tubulointerstitial antigen (TINag) on proximal tubule's BM is the major target of anti-TBM antibody-mediated TIN in humans [43]. Anti-TBM antibodies can be seen in association with drug-induced TIN and more commonly in the setting of renal transplantation due to the presence of foreign antigens in the transplanted kidney [44].

Proteinuria-Induced Tubular Cell Injury

The potential inflammatory and fibrogenic role of abnormal glomerular filtrate should also be considered. In glomerular injury the extrusion of plasma contents directly into the adjacent tubulointerstitium results in inflammation and scarring [45]. Proteinuria is an important factor in progression of tubulointerstitial disease. Mechanisms underlying nephrotoxic injury induced by excessive proteinuria involve numerous pathways of cellular damage. Urinary proteins activate proximal tubular cells into acquiring a pro-inflammatory phenotype [46]. Several in vitro studies have demonstrated that certain urinary proteins (particularly albumin) can stimulate proximal tubular cells to synthesize chemokines, such as monocyte chemoattractant protein-1 (MCP-1), RANTES, and others that recruit monocytes and T cells and interleukin-8 that attract neutrophils [47, 48]. Autophagy is one of the upregulated mechanisms of protein-induced renal injury as well [49]. Dose- and duration-dependent induction of apoptosis was also demonstrated in cultured proximal tubular cells after protein overload [50].

Tubulointerstitial Fibrosis Development

In the majority of patients, tubulointerstitial inflammation is controlled by the immune system and does not lead to progressive damage. However, if inflammation fails to terminate and self-limiting healing does not occur, a maladaptive process typically leads to abnormal healing, chronic inflammation, and fibrosis. Progressive tubulointerstitial fibrosis is the final common pathway for all kidney diseases leading to CKD [51]. Fibrogenesis initiates in small areas of inflammation and then expands to become diffuse if profibrotic drivers persist [52]. The process of tubulointerstitial fibrosis involves the loss of renal tubules and the accumulation of fibroblasts and matrix proteins, such as collagen (types I–V and VII), fibronectin, and laminin [53].

Fibroblasts in tubulointerstitium may arise from transformation of tubular epithelium in the process of epithelial–mesenchymal transformation (EMT) [54], activated by immune-mediated mechanisms and various cytokines secreted by interstitial cells. A number of proteins, including Wnt proteins, integrin-linked kinases, IGF-1 and IGF-2, epidermal growth factor (EGF), fibroblast growth factor-2 (FGF-2), and TGF-β, are among the modulators of EMT [55]. One of the strongest morphogenic cytokines driving tubulointerstitial fibrosis is angiotensin II [56]. Vascular pericytes may also differentiate into fibroblasts [57]. Transformed fibroblasts migrate to interstitium influenced by chemoattractants and begin to deposit fibronectin matrix and collagen. Interstitial M1 inflammatory and reparative profibrotic M2 macrophages interact with fibroblasts via various cytokines, determining the extent of renal fibrogenesis.

In parallel to fibrosis formation, the effect of cytokines on tubular cells can result in their atrophy and destruction. Thus, tubular atrophy and interstitial fibrosis coexist. Tubular damage plays a central role in the progression of CKD. The central role in this process is thought to belong to proximal tubule as was recently reviewed [42]. Activation and dedifferentiation of proximal tubular cells mediate multiple components of the fibrogenic response. Remnant nephron hypertrophy, alteration in tubuloglomerular feedback, impaired autoregulation of renal blood flow, and disconnection of proximal tubuli from glomeruli (“atubular glomeruli”) are well-recognized interrelated consequences of tubulointerstitial fibrosis that lead to CKD progression.

Chronic Hypoxia in Fibrosis

Hypoxia contributes directly to the progression of tubulointerstitial fibrosis by simulating EMT and promoting matrix accumulation from new fibroblasts [58]. Interstitial fibrosis reduces peritubular vascular supply leading to starvation of tubules, tubular atrophy, and loss. Hypermetabolism of remaining tubular cells requires increased oxygen consumption further promoting hypoxia [59].

Hypoxia exacerbates ER stress, leading to the autophagy of proteins and mitochondria and release of reactive oxygen species (ROS) [42]. One of ROS actions is the stabilization and generation of hypoxia inducible factor (HIF), which promotes extracellular matrix expression [60], by profibrotic factors expression stimulation [61]. Cyanotic heart disease can be a clinical example of chronic hypoxia. Nephropathy has long been recognized as a potential complication of long standing cyanotic congenital heart disease [62]. Animal models of hypoxia-induced changes in congenital heart disease demonstrate that renal tubular structure is abnormal and interstitial fibrosis is present after a relatively short period of tissue hypoxia (28 days in rats) [63].

Epidemiology

There are no reliable data on the incidence and prevalence of TIN in either adults or children. For adults, the proportion of TIN in all biopsies of 0.5–2.6% can be estimated from the evaluation of biopsy registers, while it is responsible for 5–19% of acute kidney injury [6]. The collection of epidemiological data is made more difficult by the fact that not all patients are biopsied, the clinical symptoms are often unspecific, and there are clear regional differences with regard to the etiology of the disease [9].

No prospective studies are available in pediatric patients. A single large center trial from North America reports on 133 biopsy-proven acute TIN cases over a period of 18 years. A pediatric single center experience over 3 years more than three decades ago, found acute TIN in seven patients, which comprised 7% of all biopsies performed over that period.[9] A recent contemporary series form a referral center in the UK reports on similar numbers (10 cases over an 8 year period) [64].

Pathology

The "gold standard" of acute TIN diagnosis is renal biopsy (Fig. 1). The characteristic finding of acute TIN is interstitial infiltration by inflammatory cells. These cells can cross tubular basement membrane (TBM) and enter tubules ("tubulitis"), which is often accompanied by degenerative tubular changes. Interstitial edema may be present, and the degree of fibrosis depends on the pathologic process persistence. The interstitial infiltrate is composed of T lymphocytes (mostly CD4^{+} and CD8^{+}), and less amount of macrophages, plasma cells, neutrophils, and eosinophils, depending on TIN etiology. Eosinophils can present in tubulointerstitial infiltrate in cases of drug-induced TIN, tubulointerstitial nephritis and uveitis (TINU), and IgG4-related kidney disease, but their absence does not exclude these diagnoses (like in the case of NSAIDs and PPI-induced TIN) [65]. Neutrophils are suggestive of an infectious etiology. Non-caseating granulomas can be occasionally found in drug-induced and sarcoidosis-related TIN [66]. Medications more commonly associated with granuloma formation include anticonvulsants, antibiotics, NSAIDs, allopurinol, immune checkpoint inhibitors, and diuretics. Glomeruli and blood vessels are typically spared. However, in NSAID-induced acute TIN, glomerular lesions such as minimal change disease or membranous nephropathy may be present, correlating with significant proteinuria.

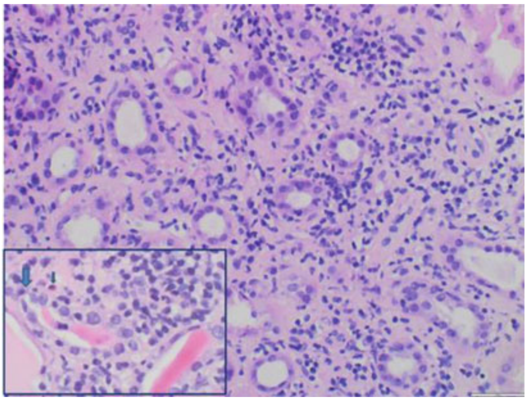

Fig. 1 Histopathological picture of acute TIN: white blood cells infiltrate the tubulointerstitial space, with increased inter tubular space (magnification: X100). Left lower quadrant: enlargement (X400): small arrow: eosinophil; large arrow: plasma cell

Immunofluorescence is typically unremarkable. Occasionally positive staining for IgG and

C3 is present on TBMs in the cases of anti-TBM antibodies mediated disease. Significant IgG4 positivity in plasma cells in interstitial infiltrate is observed with IgG4-related kidney disease [67].

Etiology

The causes of tubulointerstitial nephritis vary. Associated, possible, and systemic diseases are known to cause interstitial nephritis. Furthermore, TIN occurs in connection with a mostly anterior uveitis in the context of the TINU syndrome (see below). If the cause of TIN cannot be revealed, it is referred to as an idiopathic form.

Drug-Induced TIN

See Table 1 for an ever-growing list of drugs associated with TIN. The most common medications associated with TIN are antibiotics, NSAID, and proton pump inhibitors [68]. A retrospective analysis of more than 1000 pediatric AKI cases revealed that exposure to NSAID (usually in the proper therapeutic dosage) was responsible for AKI in and 6.6% of cases, when excluding complex patients with multifactorial AKI. Chronic use of PPI has been shown in several large population studies (involving adults) to be associated with incident CKD [69]. Using two large adult patients' databases and comparing exposure to PPIs vs H2 blockers or by propensity score matching, use of PPIs conferred an increased risk for CKD [65].

DRESS Syndrome

Drug reaction with eosinophilia and systemic symptoms (DRESS) is a rare but potentially fatal adverse drug reaction with variable renal involvement. The most common medications associated with this entity are anticonvulsants and allopurinol. DRESS diagnosis can be difficult if not suspected, since there could be a significant lag period (weeks to months) between beginning of treatment and the appearance of symptoms. TIN has also been described as the renal manifestation in DRESS [70].

Secondary Immune Acute TIN

Systemic Lupus Erythematosus (SLE)

SLE is the most important cause of acute TIN seen in association with glomerulonephritis in children. In few cases a predominant acute TIN has been described in SLE patients [71]. Tubulointerstitial immune deposits may be present in up to 60% of SLE patients who are biopsied and correlate with both severity of interstitial inflammation and degree of functional renal impairment. As is the case with other glomerular diseases, severe tubulointerstitial involvement with fibrosis is a poor prognostic indicator for renal function [72].

Sjogren Syndrome

Primary SS (pSS) is a chronic autoimmune disorder characterized by lymphocytic infiltration of exocrine glands, resulting in significant loss of secretory function, usually the salivary and lacrimal glands, resulting in oral and eye dryness. The course of the disease is also characterized by the occurrence of extraglandular features, with frequent multi-organ involvement, including the kidney. However, overt renal disease is a rare event during pSS [73]. In a nationwide survey from France of patients with pSS and with biopsy-proven renal involvement ($n = 95$), the lowest quartile of patients was less than 18 years old. In this cohort, 75% of kidney biopsies showed TIN [74]. In many cases renal tubular acidosis is seen [75].

TINU

Young patients with uveitis should be screened for renal tubulointerstitial co-involvement, using urine low molecular weight proteinuria and serum creatinine testing [76]. Vice versa, all patients with TIN should be screened by an ophthalmologist for uveitis. The co-appearance of inflammatory conditions in two remote organs speaks in favor of an autoimmune tendency. Indeed, correlation between IL10 gene (responsible for acute inflammatory response

Table 1 List of medications associated with acute TIN. * Pediatric cases reported

Anti-inflammatory drugs and analgesics
- Benoxaprofen
- Diclofenac
- Diflunisal
- Fenoprofen
- Floctafenine
- Glafenine*
- Ibuprofen*
- Indometacin
- Ketoprofen
- Mefenamic acid
- Naproxen*
- Niflumic acid*
- Phenazone
- Phenylbutazone
- Piroxicam
- Rofecoxib
- Sulfinpyrazone
- Sulindac
- Suprofen
- Tolmetin*
- Zomepirac

B-lactam antibiotics
- *Cephalosporins*
  - Cefaclor
  - Cefotaxime
  - Cefoxitine
  - Ceftriaxone
  - Cephalexin
  - Cephaloridine
  - Cephalothin
  - Cephradine
- *Penicillins and derivatives*
  - Penicillin G*
  - Amoxicillin
  - Ampicillin*
  - Carbenicillin
  - Cloxacillin*
  - Flucloxacillin
  - Methicillin*
  - Mezlocillin
  - Nafcillin*
  - Piperacillin-tazobactam
  - Oxacillin

Other antibiotics
- Azythromycin
- Aztreonam
- Chloramphenicol
- Ciprofloxacin
- Clarithromycin
- Co-trimoxazole
- Erythromycin*
- Ethambutol
- Gentamycin
- Isoniazid
- Lincomycin
- Loracarbef*
- Nitrofurantoin
- Norfloxacin
- Piromidic acid
- Polymyxin sulfate
- Rifampin
- Spiramycin
- Sulfonamides*
- Sulfadiazine
- Trimethoprim-sulfamethoxazole*
- Vancomycin
- Trimethoprim-sulfamethoxazole*
- Vancomycin

Antivirals
- Acyclovir
- Indinavir

Tetracyclines
- Minocycline*

Anticonvulsants
- Carbamazepine*
- Lamotrigine
- Phenobarbital*
- Phenytoin*
- Sodium valproate*

Proton pump inhibitors
- Omeprazole
- Lansoprazole
- Esomeprazole
- Pantoprazole

Diuretics
- Chlorthalidone
- Ethacrynic acid
- Furosemide
- Thiazides
- Tienilic acid
- Triamterene

Antineoplastic agents
- Adriamycin
- Bevacizumab
- Carboplatin
- Cytosine arabinoside
- Ifosfamide
- Immune-check point inhibitors
- Interferon
- Methotrexate
- Tyrosine kinase inhibitors

5-aminosalicylates
- Mesalazine*
- Sulfasalazine

Other drugs
- Aldomet
- Allopurinol
- Amlodipine
- Amphethamine
- Anti-CD4 antibodies
- Aspirin
- Azathioprine
- Captopril
- Chlorprothixene
- Cimetidine
- Clofibrate
- Clozapine
- Coumadin
- Crack cocaine
- Creatine
- Cyclosporine*
- Diazepam
- Doxepin
- Etanercept
- Haloperidol
- Haloperidol
- Heroin
- Herbal medicines (aristolochic acid)
- Imipramine
- Pamidronate
- Phenazone
- Phenindione*
- Phenylpropanolamine*
- Propranolol
- Propylthiouracil
- Protease inhibitors
- Quinine
- Ranitidine
- Streptokinase

downregulation) polymorphisms and TINU was found in a Finnish cohort [77]. Uveitis and TIN may not appear at the same time. Another study from Finland reported in 26 children with an original diagnosis of acute TIN that uveitis may develop late and without recurrence of renal dysfunction [78]. In a retrospective patient series from France, which included adults and adolescents, oral corticosteroid therapy was associated with less relapses of uveitis, but did not affect renal function course [79].

Inflammatory Bowel Disease (IBD)

IBD may cause different renal manifestations, including obstructive uropathy and glomerular diseases (mainly IgA nephropathy and minimal change disease). TIN was found in 19% of kidney biopsies, in most of them in association of mesalazine use, the commonest nonsteroidal anti-inflammatory agent used in IBD [80].

Kawasaki Disease (KD)

Even though sterile pyuria is a common manifestation of KD, AKI has rarely been reported, usually in association with acute heart failure and multiple organ dysfunction. However, a minority of case reports include TIN as an etiology for renal dysfunction [81].

Allograft Nephropathy

This topic is reviewed in Chap. “Allograft Nephropathy” in this book.

IgG4-Related Kidney Disease

IgG4-related disease (IgG4-RD) is a systemic fibro-inflammatory disorder involving almost any organ in the body. A literature search identified 25 children with this disease. The most common manifestations included orbital disease (44%) and autoimmune pancreatitis (12%) [82]. TIN is the commonest form of renal involvement in IgG4-related disease. It is characterized by a dominant infiltrate of IgG4-positive plasma cells in the interstitium and storiform fibrosis. However, IgG4 positive plasma cells may also be seen in SLE, Sjogren syndrome, and ANCA-associated vasculitis [83].

Toxic Nephropathy[1]

Numerous medical and non-medical substances may be associated with AKI by different mechanisms, and its clinical picture may be similar to acute TIN. This topic is reviewed extensively in another book’s chapter, but several medications and substances will be mentioned in this chapter too.

Aristolochic Acids

The previously termed Chinese herb nephropathy and Balkan nephropathy entities are nowadays known to be associated with the ingestion of aristolochic acid, and it is now termed aristolochic acid nephropathy (AAN). AAN may cause urothelial cancer as well as CKD [84]. Its clinical presentation may be acute or chronic [85], and it has also been described in children and adolescents [86].

Old and Novel Anti-Cancer Drugs

It is important to remember that some of the medications used in cancer (including Ifosfamide, BCG, tyrosine kinase inhibitors, premetrexed, and oxaliplatin) may impair kidney function not just through a tubulo-toxic mechanism but also through TIN, some of them acute and reversible [87]. Use of immune checkpoint inhibitors (anti CTLA4 and PD1 inhibitors) may cause different renal side effects, including AIN [88]. Even though the use of these medications group has been increasing significantly in pediatrics in the last years [89], there have been no reports yet on renal side effects by these novel agents.

Infection Associated TIN[2]

This topic is also extensively reviewed in another book chapter.

Hantavirus infections are endemic worldwide and may cause AKI in association with an epidemic-infectious pattern. It is usually associated with thrombocytopenia. In Western Europe the Puumala subtype of hantavirus is common. A patient series from Germany compared the clinical symptoms and course in 295 adults and 22 children. AKI, thrombocytopenia, sudden onset of fever, and back/loin pain were similarly common in both adults and children. Whereas adults presented more frequently with arthralgia and visual disturbances, abdominal pain and nausea/vomiting could be detected more often in children. No significant differences were found in the incidence of complications (hemodialysis, long-term outcome of kidney function, length of hospital stay) [90].

---

[1] There is a chapter on “Allograft Nephropathy” by Scott Sutherland

[2] See Chap. 26, “Infections That Affect the Kidney (Non-viral),” by V Koch and 27, “Viral Infections and the Kidney,” by P Ray

Leptospira

TIN is a common clinicopathological finding in leptospirosis. Its renal clinical manifestations include nonoliguric AKI, hypokalemia, sodium, and magnesium wasting. Primary injury of the proximal convoluted tubules is regarded as the hallmark of the kidney in leptospirosis [91].

Group A Streptococcus

Acute TIN secondary to streptococcal infection has been seldom reported in past years. However, TIN was first described as a clinical entity in patients with scarlet fever. Ellis et al. described 13 children with biopsy-proven TIN, seven of whom had clinical and/or laboratory signs of streptococcal infection [92]. Histopathological analysis in this entity showed no staining for either immunoglobulins or complement factors, but immunohistochemical studies may reveal the presence of streptococcal pyrogenic exotoxin B in the tubulointerstitial compartment.

TIN of Unknown Etiology

Mesoamerican Nephropathy

This disease affects mainly agricultural workers and has been originally described in central America, but was later described also in Egypt, India, and Sri Lanka. Disease etiology was originally suspected to be due repeated dehydration episodes, and most affected patients presented already at the CKD stage. In a small prospective study of patients with unexplained AKI living in central America, 11 consecutive patients underwent a kidney biopsy, which revealed primary interstitial nephritis with intact glomeruli [93], suggesting that this disease undergoes initially through an active, inflammatory phase. This emphasizes again the overlap between non-glomerular AKI, toxic nephropathy, and “allergic” TIN.

Genetic Causes of Tubulointerstitial Diseases

Several genetic factors have been associated with development of chronic forms of TIN that inevitably lead to end-stage renal disease [94, 95, 96, 97]. These disorders are reviewed in other chapters of the book [98].

Clinical Presentation

Tubulointerstitial nephritis often presents with unspecific clinical symptoms. A late diagnosis with delayed initiation of therapy and poor outcome can be the result.

Acute TIN is responsible for about 10% of AKI cases. Sometimes TIN may be the presenting symptom of a systemic disease (including TINU, but also other rheumatic diseases), which will develop within months to years from the initial diagnosis of acute TIN [99].

The clinical manifestations of TIN are variable, and differentiation between acute and chronic TIN may be difficult. Renal impairment severity may range from mild, as asymptomatic urinary abnormalities, mild azotemia and nonoliguric or oliguric AKI. These nonspecific clinical findings emphasize the need for a renal biopsy to make a definitive diagnosis in questionable cases. However, in children with mild impairment of kidney function, if improvement in kidney function is noticed after withholding the suspected offending agents or, if a clear-cut clinical picture of acute allergic TIN is seen (leading to therapy initiation), a biopsy is not needed. Symptoms may develop several days and at times weeks after exposure to the inciting agent. Systemic manifestations of a hypersensitivity reaction, such as fever, rash, and arthralgia, are variable findings. Although these symptoms are more likely to occur in drug-induced acute TIN, it is seldom (only in 10%) seen as a triad [100]. The rash may be maculopapular, morbilliform, or pruritic-urticarial, and preferentially affect the trunk and proximal extremities. Arthralgia is sometimes seen. Acute TIN associated with infection may present with extrarenal manifestations, such as fever and sore throat, fatigue, anorexia, weight loss, nausea, and vomiting. Flank pain and even hematuria may be seen in the minority of cases [101]. Hypertension and edema are seldom noted, except in specific drug-induced lesions, such as the nephrotic syndrome associated with nonsteroidal anti-inflammatory drugs (NSAIDs), or in TIN secondary to glomerular disease.

Decrease in glomerular filtration secondary to the tubular injury results in elevated serum creatinine concentration. Urinalysis may show active (leukocytes, red blood cells) or relatively bland changes. Associated non-kidney abnormalities include normochromic, normocytic anemia, which at times may be hemolytic [102]. Leukocytosis may occur, and peripheral eosinophilia is seen in a minority of patients (in some of them as part of the drug reaction, eosinophilia and systemic symptoms syndrome – DRESS). Elevated serum IgE titers have been reported in less than 50% of biopsy-proven cases and are suggestive of drug-induced TIN. Anti-DNA antibodies, antinuclear antibodies, and complement levels are normal in most forms of TIN, unless associated with a systemic autoimmune disorder. Renal ultrasound examination usually demonstrates normal or enlarged kidneys and at times hyperechogenicity, depending on the extent of tubulointerstitial inflammation and edema. Gallium citrate scanning may be useful in distinguishing acute TIN from other common causes of AKI. However, increased uptake on gallium scan is a relatively nonspecific finding and may be seen in cases of allograft rejection, acute pyelonephritis, and severe minimal change nephrotic syndrome. Therefore, this modality is no longer used and many times TIN can only be made by renal biopsy.

Urinary Biomarkers

Since renal tubular epithelial cell damage by infiltrating inflammatory cells is the predominant pathophysiology, laboratory abnormalities in TIN may reflect injury to specific nephron segments involved in the inflammatory process. Proximal tubule injury results in Fanconi syndrome with impaired urinary reabsorption of glucose, bicarbonate, phosphorus, amino acids, alpha-1 and β2-microglobulin, and uric acid. Damage to the loop of Henle may result in magnesium and sodium losses. Distal tubular lesions result in renal tubular acidosis, impaired potassium excretion, sodium wasting, and a urine-concentrating defect.

Even though kidney biopsy remains the gold standard for TIN diagnosis, some classical and novel biomarkers for TIN may serve in the diagnosis, prognosis, and follow-up of this disease, as recently reviewed [103]. Sterile leukocyturia is an almost universal finding in drug-related and especially in antibiotic-related acute TIN [104]. Due to the type IV hypersensitivity basis of drug-induced acute TIN, eosinophiluria was considered a classical biomarker in acute TIN, but it is no longer considered sensitive or specific [105]. Detection of LMW proteins in the urine may be signs of ongoing renal tubulointerstitial inflammation or fibrosis, or both, which supports the use of these biomarkers in follow-up of activity of TIN [106]. Urinary β2M and serum creatinine levels were shown to be sensitive and relatively simple diagnostic screening tools for detecting TINU syndrome in young children with uveitis [76]. Monocyte chemoattractant protein-1 (MCP-1), an important chemoattractant involved in interstitial inflammation, was evaluated in several works. Higher urinary MCP-1 levels were shown in a cohort of 40 patients with drug-induced ATIN compared to controls, in correlation with the severity of the acute lesions in kidney biopsies from these patients [107]. In another cohort of 113 acute TIN patients from different causes, higher MCP-1 serum and urine levels were also detected [108]. Urinary MCP-1 concentration finely correlated with the amount of tubulointerstitial but not with the glomerular infiltrate in a cohort of patients with glomerular autoimmune diseases [109]. In humans with ureteropelvic junction obstruction, urinary MCP-1 is increased and improves after obstruction surgical alleviation [110]. Higher serum and urine levels of tumor necrosis factor alpha (TNF-α) and urinary IL-9 have been reported in patients with acute TIN [111] [112]. The value of serum TNF-α levels in the follow-up of a case of TINU dramatically decreased during the first week after treatment initiation.113 Other unspecific tubular AKI biomarkers have also been evaluated in acute TIN. Urinary NGAL, NAG, and α1-microglobulin levels were found to be significantly elevated in patients with drug-induced TIN compared to controls.106 Urinary KIM-1 is a specific biomarker for acute renal tubular injury, including in patients with TIN, whereas urinary soluble complement terminal attack complex (sC5b-9), a marker of complement activation, is valuable in reflecting severe interstitial inflammation. The combination of these two biomarkers may be used to identify patients with TIN at an acute injury stage.114

Cellular activation markers on the surface of lymphocytes after incubation with the offending drug – such as CD25, CD69, or human Leukocyte antigen (HLA)-DR – may indicate hypersensitivity.115 Activation of T cells after drug exposure triggers a specific pattern of cytokine secretion that can be detected, using enzyme- linked assays. Release of high amounts of IL-5, IL-10, and IFN-γ, in the setting of hypersensitivity has been reported.116

Diagnostic Approach

Figure 2 provides an overview on a possible diagnostic pathway, primarily based on an ultrasound examination, urinary dipstick analysis, and measurement of urinary alpha-1 or beta-2 microglobulin/ creatinine ratios in children with AKI. After excluding other causes like pre-renal failure, glomerular disease, or urosepsis, in most cases a renal biopsy is needed to diagnose TIN, unless a clearly drug-induced cause can be found, that can be treated by drug discontinuation. After diagnosis of TIN, efforts should be done to identify the cause for TIN and consequently, the treatment of TIN and/or the underlying cause/disease could be started.

Treatment

The most important aspect in the therapy of tubulointerstitial nephritis is its early diagnosis.[1] With the drug-induced forms, a complete or partial recovery of kidney function can be expected if the TIN is recognized in good time and the drug causing the problem is discontinued immediately. The likelihood of recovery in kidney function depends largely on the duration of the kidney damage prior to diagnosis and should ideally be less than 2 weeks. About a third of patients develop chronic kidney impairment.117 In the case of systemic illnesses or infections, treating the underlying illness has priority.

The role of corticosteroids in the therapy of tubulointerstitial nephritis is controversial. There are no randomized, controlled studies on the use of corticosteroids, and retrospective studies in adults have provided contradicting results. For example, a study on 60 adult patients with tubulointerstitial nephritis of different etiologies could not demonstrate any effect of corticosteroid treatment on the outcome (measured as serum creatinine 1, 6, and 12 months after the onset of the disease).118 In contrast, a multicenter retrospective study with 61 adult patients with drug-induced TIN showed a significantly higher risk of permanent impairment of kidney function and chronic dialysis in patients who were not treated with corticosteroids. There was also a significant correlation between the latency to the start of steroid treatment and long-term kidney function: an interval of more than 7 days between discontinuation of the drug and the start of steroid therapy increased the risk of incomplete recovery of kidney function.119 In a prospective pediatric study with 17 patients, corticosteroids were shown to accelerate the recovery of kidney function, especially in patients with severe renal impairment.120

There is no consensus on the duration and dosage of corticosteroid therapy, neither for adults nor for children. Common practice is oral steroid therapy in tapering doses that, depending on the course, extend over several weeks. Intravenous steroid bolus therapy can precede oral treatment if the course is severe.

Mycophenolate mofetil (MMF) is used successfully in individual cases in patients with steroid-resistant courses or contraindications for corticosteroids.121 To date, however, there is too little evidence for the widespread use of MMF.

severe DRESS in spite of offending drug withdrawal and systemic corticosteroid therapy, who benefited substantially from a 1 to 2 g/kg course of IVIG.122

Prognosis

The long-term prognosis for ATIN is generally favorable, with full kidney recovery within 1 month in most cases.123 However, some patients may develop progressive chronic kidney disease. Immunosuppressive therapy may be indicated for severe or prolonged disease.

In summary: Early diagnosis is crucial for therapy and improved prognosis of TIN. Clinical symptoms such as fever, fatigue, nausea, vomiting, and volatile rash in combination with increased kidney function parameters and characteristic urine findings (no hematuria, trace proteinuria by dipstick, but significant α1/β2 microglobulinuria) indicate tubulointerstitial nephritis. The medical history should include questions about previous medication use (especially antibiotics, NSAID), symptoms of infection, chronic diseases, and ocular symptoms. Discontinuation of the triggering substance or treatment of the underlying disease is of crucial importance in the therapy of TIN.

Oral and intravenous corticosteroids are widely used as drug therapy, although randomized controlled studies on steroid therapy of TIN do not yet exist.

Abstract

Dysnatremias are among the most common electrolyte abnormalities encountered in hospitalized patients. Proper fluid management and early detection are important in the prevention and treatment of dysnatremias. Virtually all acutely ill patients are at risk for developing hyponatremia due to numerous hemodynamic and non-hemodynamic stimuli for arginine vasopressin (AVP) release. One of most common causes of hyponatremia in hospitalized patients is the syndrome of inappropriate antidiuresis (SIAD). An elevated fractional excretion of urate is helpful in establishing a diagnosis of SIAD. A major contributing factor to the development of hospital-acquired hyponatremia is the administration of hypotonic fluids. Recent clinical practice guidelines have recommended isotonic maintenance fluids for the prevention of

hospital-acquired hyponatremia. Hyponatremic encephalopathy is the most serious complication of hyponatremia. Consensus guidelines have recommended intermittent bolus therapy with 3% sodium chloride for the treatment of hyponatremic encephalopathy. Excessive therapy of severe and chronic hyponatremia can also lead to neurologic injury due to cerebral demyelination. Hospital-acquired hypernatremia occurs in patients who have restricted access to fluids in combination with ongoing free water losses. A group at high-risk for developing hypernatremia in the outpatient setting is that of the breastfed infant due to insufficient lactation. Patients at risk for severe hospital-acquired hyponatremia are those with diabetes insipidus. A useful test for distinguishing central from nephrogenic diabetes insipidus is plasma copeptin testing. Copeptin can be used as a surrogate marker of AVP as it is easier and more reliable to measure.

Water Homeostasis

The plasma osmolality is maintained within a narrow range, 275–290 mOsm/kg. The hypothalamus senses alterations in osmolality, which leads to changes in thirst and release of arginine vasopressin (AVP) in order to return the osmolality to normal. Osmoreceptors are located in the anteroventral third ventricle of the hypothalamus and AVP is synthesized in the vasopressinergic neurons of supraoptic and paraventricular nuclei of the hypothalamus [1]. AVP is stored and subsequently released from the posterior pituitary (Fig. 1). The gene that encodes AVP is located on chromosome 20. The biosynthesis of AVP proceeds by way of a polypeptide precursor. This prohormone contains the AVP moiety, a protein known as neurophysin II (NPII) and a glycoprotein. This prohormone ultimately folds and dimerizes and is cleaved into AVP, where it is stored in the posterior pituitary until it is release into the cavernous sinus and superior vena cava [2].

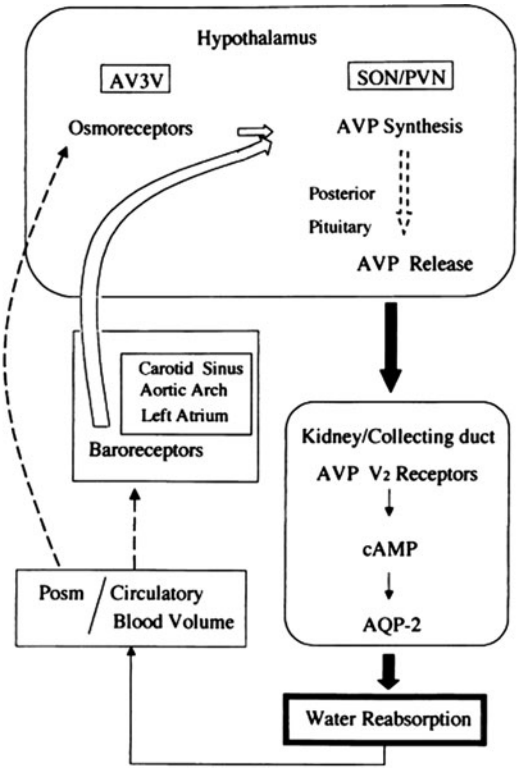

Fig. 1 AVP and water homeostasis: Anteroventral third ventricle (AV3V), supraoptic and paraventricular nuclei (SON/PVN). (From: Ishikawa SE, Schrier RW. Pathophysiological roles of arginine vasopressin and aquaporin-2 in impaired water excretion. Clin Endocrinol (Oxf) 2003;58(1):1–17) [1]

AVP is the primary determinant of free water excretion. Its major renal affect is to increase water permeability in the medullary and collecting tubules via the insertion of the aquaporin 2 (AQP2) water channel on the apical surface of the cortical collecting duct (Fig. 1) [3]. The action of AVP is mediated via the vasopressin V2 receptor that is located on the basolateral surface of the principal cells. The V2 receptor is coupled to a guanine-nucleotide-binding protein, Gs. Binding of AVP to the V2 receptors results in activation of adenylate cyclase with increase in cAMP and activation of c-AMP-dependent protein kinase A (PKA). Activated PKA phosphorylates the serine residue at the C-terminus of the AQP2 protein, which leads to insertion of AQP2 on apical surface of the principal cells of the cortical collecting duct resulting in increased water permeability. Water movement across the basolateral membrane is facilitated by AQP3 and AQP4. Any defect along this pathway will prevent AQP2 expression and will result in a renal concentrating defect. On the other hand, process that increase the expression of AQP2 result in impaired ability to excrete free water.

Hyponatremia

Hyponatremia, serum sodium <135 mEq/L, is one of the most common electrolyte disorders in both ambulatory and hospitalized patients. The incidence of hyponatremia is approximately 2% in the general population, increasing with age [4], and 15% in unselected hospitalized children [5]. The majority of hyponatremia is hospital-acquired- and related to hypotonic fluid administration, occurring in approximately 30% of children receiving intravenous fluids [6]. Hyponatremia is an independent prognostic factor for risk-adjusted mortality in ambulatory and hospital settings, and particularly in patients with end-stage liver disease, congestive heart failure, pneumonia, and advanced kidney disease [7]. Mild and chronic hyponatremia can result in subtle neurologic impairment and can lead to increased bone fragility resulting from bone demineralization in both children and adults [8, 9]. Hyponatremic encephalopathy is the most serious complication [10].

Pathogenesis

The body's primary defense against hyponatremia is the kidney's ability to generate dilute urine and excrete free water. Rarely is excess ingestion of free water alone the cause of hyponatremia, as an adult with normal renal function can typically excrete over 15 L of free water per day. It is also rare to develop hyponatremia from excess urinary sodium losses in the absence of free water ingestion. In order for hyponatremia to develop it requires relative excess of free water intake in conjunction with an underlying condition that impairs urinary free water excretion (Table 1). Renal water handling is primarily under the control of AVP that is produced in the hypothalamus and released from the posterior pituitary [11]. AVP release impairs water diuresis by increasing the permeability to water in the collecting tubule. There are numerous hemodynamic and non-hemodynamic stimuli for AVP release, and this places almost all acutely ill patients at risk for hyponatremia [12]. The body will attempt to preserve the extracellular volume at the expense of the serum sodium, and therefore a hemodynamic stimulus for AVP production will override any inhibitory hypo-osmolar effect of hyponatremia [13]. There are numerous stimuli for AVP production that make many hospitalized children at risk for hyponatremia due to the syndrome of inappropriate antidiuresis (SIAD).

Diagnosis

Before embarking on a therapeutic regimen, it is vital to confirm that hyponatremia is associated with hypoosmolality. Hyponatremia can be associated with either normal or elevated serum

Table 1 Disorders in impaired renal water excretion

1. Effective circulating volume depletion
(a) Gastrointestinal losses: vomiting, diarrhea
(b) Skin losses: cystic fibrosis
(c) Renal losses: salt-wasting nephropathy, diuretics, cerebral salt wasting, hypoaldosteronism
(d) Edematous states: heart failure, cirrhosis, nephrosis, hypoalbuminemia
(e) Decreased peripheral vascular resistance: sepsis, hypothyroidism
2. Thiazide diuretics
3. Renal failure
(a) Acute
(b) Chronic
4. Non-hypovolemic states of ADH excess
(a) Syndrome of Inappropriate of Antidiuresis (SIAD)
(b) Nausea, emesis, pain, stress
(c) Postoperative state
(d) Cortisol deficiency
5. Nephrogenic Syndrome of Inappropriate Antidiuresis (NSIAD)

osmolality (Fig. 2). Common reasons for the latter are hyperglycemia, severe hyperproteinemia, or hyperlipidemia. Hyperglycemia results in hyperosmolality with translocation of fluid from the intracellular to the extracellular space, resulting in a 1.6 mEq/L fall in the serum sodium for every 100 mg/dL elevation in blood glucose concentration above normal [14]. Severe hyperlipidemia, hypercholesterolemia, hyperproteinemia, or radiocontrast and IV immunoglobulin infusions can displace plasma water, resulting in a decreased sodium concentration (pseudohyponatremia) with a normal serum osmolality [15]. Serum sodium is currently measured by either direct or indirect-reading ion-selective electrode potentiometry [16]. The direct method will not result in a diagnosis of pseudohyponatremia, as it measures the activity of sodium in the aqueous phase of serum only. Whole blood sodium, blood gas, and point of care analyzers employ the direct methods and are not subject to pseudohyponatremia. Most laboratories use the indirect method, which can result in pseudohyponatremia as the specimen requires a predilution. If hyponatremia is associated with hypoosmolality (true hyponatremia), the next step is to measure the urinary osmolality to determine if there is an impaired ability to excrete free water (osmolality >100 mOsm/kg).

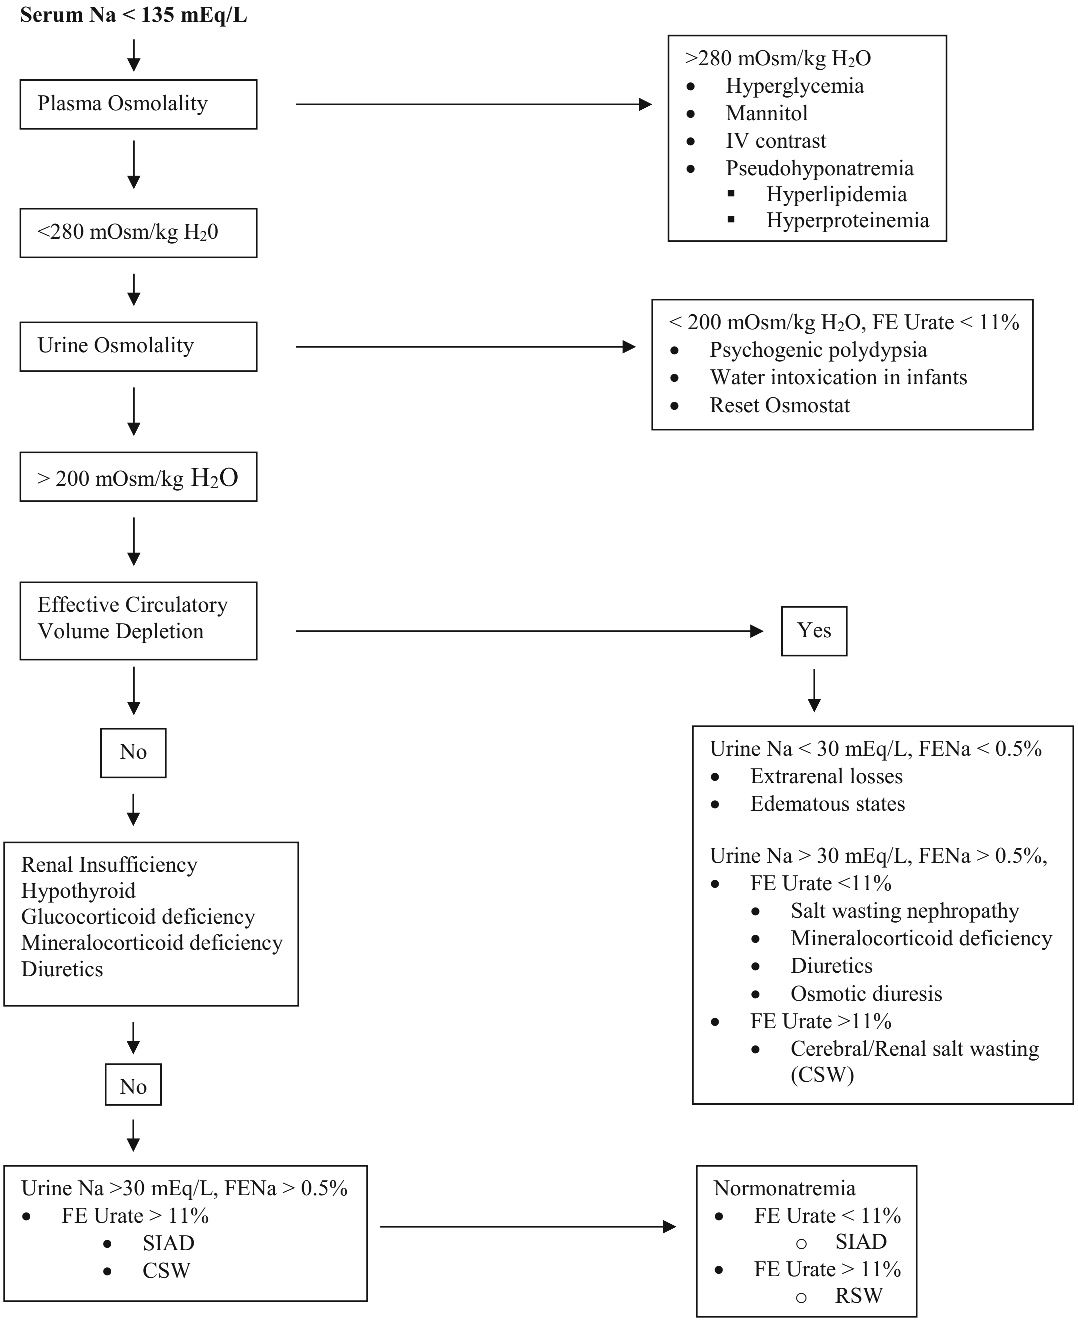
The information that is most useful in arriving at a correct diagnosis of hyponatremia is a detailed history of fluid balance, weight changes, medications (especially diuretics), and underlying medical illnesses. Hyponatremia is usually a multifactorial disorder and a detailed history helps identify sources of salt and water losses, free water ingestion, and underlying illnesses that cause a non-osmotic stimulus for vasopressin production. An assessment of the volume status on physical examination and measuring the urinary electrolytes and osmolality is helpful. In patients in whom hyponatremia is due to salt losses (e.g., diuretics), signs of volume depletion may be absent on examination, as the volume deficit may be nearly corrected due to oral intake of hypotonic fluids if the thirst mechanism is intact, or in patients receiving hypotonic IV fluids.

In general, urinary sodium concentration less than 30 mEq/L is consistent with effective circulating volume depletion, while urine sodium greater than 30 mEq/L is consistent with renal tubular dysfunction, use of diuretics, or SIAD [17]. Numerous factors can affect the urine sodium concentration, making interpretation difficult. Therefore, the timing of the urinary measurements in relation to therapy with diuretics, IV fluid boluses, or fluid and sodium restriction is important. In some cases, estimation of intravascular volume status by measurement of the central venous pressure or sonography of the inferior vena cava may be helpful.

SIAD

SIAD is one of the most common causes of hyponatremia in hospitalized children [18]. The causes are numerous, and virtually every hospitalized patient should be considered at risk of SIAD. SIAD is most often the result of central nervous system disorders, pulmonary disorders, malignancies, and medications. Many common disorders are associated with SIAD, such as pneumonia, bronchiolitis, asthma, positive pressure ventilation, CNS infections, and head trauma. Elevated blood levels of AVP and hyponatremia are associated with febrile illnesses, inflammation, and infections. Numerous medications are associated, including anticonvulsants, antidepressants, antipsychotics, opioids, chemotherapeutic agents, proton pump inhibitors, nonsteroidal anti-inflammatory agents, and recreational drugs. Chief medications associated with SIAD in children are carbemazepine, oxcarbazepine, vincristine, and cyclophosphamide. Common physiological stimuli for AVP release that can lead to an SIAD-like state are nausea, vomiting, pain, stress, hypoxia, and hypoglycemia [19]. Postoperative hyponatremia is frequently associated with an SIAD-like state due to numerous stimuli for AVP production including pain, stress, nausea, vomiting, opioids, and positive pressure ventilation [20, 21]. Exercise-associated hyponatremia is reported in children and collegiate athletes [22–24].

The hallmarks of SIAD are: mild volume expansion with low to normal plasma concentrations of creatinine, urea, uric acid, and potassium;



Serum Na < 135 mEq/L
Plasma Osmolality
>280 mOsm/kg H2O
Hyperglycemia
Mannitol
IV contrast
Pseudohyponatremia
Hyperlipidemia
Hyperproteinemia
<280 mOsm/kg H20
Urine Osmolality
< 200 mOsm/kg H2O, FE Urate < 11%

Fig. 2 Evaluation of hyponatremia

impaired free water excretion with normal sodium excretion which reflects sodium intake [25]; and hyponatremia that is relatively unresponsive to sodium administration in the absence of fluid restriction.

There are no urinary or plasma biomarkers that have a sufficiently high sensitivity and specificity to diagnose SIAD, independent of clinical assessment. Measurements of AVP or copeptin, a surrogate marker of vasopressin, have not proved useful for the diagnosis [26, 27]. The biochemical parameters suggestive of SIAD in adults include: spot urine sodium concentration >30 mEq/L, fractional excretion of sodium >0.5%, fractional excretion of urea >55%, fractional excretion of urate (FEUrate) >11%, and plasma uric acid <4 mg/dl (Fig. 2) [17]. The specificity and sensitivity of these biomarkers have not been evaluated in children. The urinary biomarker most specific for diagnosing SIAD is an elevated FEUrate [27, 28]. FEUrate is unlikely to be elevated with diuretic use or adrenal insufficiency, whereas urinary sodium biochemistries may be high. Adult parameters for FEUrate cannot be used in infants and children with renal disease, as they have higher levels [29].

Cerebral Salt Wasting Syndrome (CSW)

Another condition that is indistinguishable from SIAD is CSW. The latter is less common, and primarily but not exclusively associated with central nervous system disease; the term renal salt wasting is more appropriate [30]. The condition is chiefly seen in neurosurgical patients, in particular adults with subarachnoid hemorrhage. CSW is best described as a syndrome of inappropriate natriuresis [31]. Inappropriate and excessive release of natriuretic peptides leads to natriuresis and volume depletion. This stimulates a secondary neurohormonal response, with increase in the renin angiotensin system and in AVP production. Signs of volume depletion are not always present, and there are no investigations that consistently distinguish CSW from SIAD at the time of presentation [30]. Natriuretic peptides are known to inhibit the renin angiotensin system and the secretion and action of AVP, and to increase GFR [32]. This complex mechanism can lead to biochemical features that are indistinguishable from those of SIAD, with normal blood urea and low uric acid, as well as normal plasma renin, aldosterone, and AVP in the setting of volume depletion. Patients with CSW have higher urine volume and sodium excretion than SIAD [33]. The severity of CSW is variable; some patients may not show hyponatremia [34].

Hospital-Acquired Hyponatremia

Hospital-acquired hyponatremia is of concern in acutely ill children as the standard of care in pediatrics had been to administer hypotonic maintenance fluids containing 0.2–0.45% sodium chloride [12, 35, 36]. The safety of this approach had never been established. Hospitalized children have numerous nonosmotic stimuli for increased production of AVP that place them at risk for hyponatremia. Critically ill children are at particularly higher risk as most have multiple nonosmotic stimuli for AVP secretion (e.g., pulmonary disorders, mechanical ventilation, intracranial injury). Hyponatremia is especially dangerous in children with underlying CNS injury such as encephalitis, where even mild hyponatremia (sodium ~130 mEq/L) may result in cerebral edema and even herniation [10]. Numerous studies have demonstrated that hypotonic fluids are associated with a high incidence of hospital-acquired hyponatremia, in both surgical and nonsurgical patients and in the intensive care unit and general pediatric ward [6, 37–39]. In 2018, the American Academy of Pediatrics issued a Clinical Practice Guideline on maintenance intravenous fluids stating that the most important measure to prevent hyponatremia is to avoid using hypotonic fluids in patients with clear risks for nonosmotic AVP secretion, and to administer isotonic saline (0.9% sodium chloride, Plasma-Lyte) instead [40]. These recommendations were based on over 20 prospective trials in ~3000 patients showing that isotonic fluids decrease the incidence of hyponatremia three to sixfold in comparison with hypotonic fluids. This has led to a practice shift with increased use of isotonic maintenance fluid in children [41].

Clinical indications to not use 0.9% sodium are primarily in disease states associated with increased free water losses, such as renal concentrating defects, voluminous diarrhea, or severe burns. Furthermore, children with neurosurgical disorders, significant congenital or acquired heart disease, hepatic or renal dysfunction, fluid overload or edema, children undergoing chemotherapy, or <28-days old may require a different maintenance fluid composition and infusion rate.

Consequences of Hyponatremia and Hyponatremic Encephalopathy

There is evidence that even mild and seemingly asymptomatic hyponatremia has deleterious consequences [7]. Hyponatremia is an independent risk factor for mortality in adults with SIAD [42]. Mild and chronic hyponatremia can results in subtle neurologic impairment leading to falls and associated bone fractures in the elderly, with increased bone fragility resulting from bone demineralization [8, 43–46]. Hyponatremia represents a significant health care burden and results in increased medical costs and hospital stays [47]. Hyponatremia might also alter the immune response, and explain the increased rate of infections in hyponatremic patients [48, 49].

The most serious complication is hyponatremic encephalopathy, which is a medical emergency that can be fatal or can lead to irreversible brain injury if inadequately treated [50]. It is important to identify patients at risk for hyponatremic encephalopathy, since this might be complicated by transtentorial herniation with death or permanent neurologic sequelae [20]. Hypoosmolality results in an influx of water into the intracellular space down a concentration gradient resulting in parenchymal cell swelling, or cytotoxic cerebral edema (Fig. 3). The brain's primary mechanism for adapting to hyponatremia is extrusion of intracellular electrolytes and osmolytes [51]. Adaptation of the brain to hyponatremia takes time; based on animal studies; it takes approximately 48 h for the brain to adapt to hyponatremia [52]. Acute hyponatremia is defined as hyponatremia of less than 48-h duration, and chronic >48-h. The brain is also vulnerable to neurologic injury from overcorrection following chronic hyponatremia [53].

While abrupt and severe hyponatremia is likely to produce brain edema, then mild and chronic hyponatremia, there are risk factors for hyponatremic encephalopathy developing at mildly hyponatremic levels or with chronic hyponatremia. Risk factors include age <16 years [54], postmenarche [20], hypoxemia [55], or underlying central nervous system disease [56]. These risk factors can either impair brain cell volume regulation or are associated with decreased intracranial capacity for brain expansion. Children are at particularly high risk for hyponatremic encephalopathy as they have a relatively larger brain-to-intracranial volume compared to adults [52, 54]. The average serum sodium in children with hyponatremic encephalopathy is 120 mEq/L [57, 58], significantly higher than in adults of ~111 mEq/L [20, 59]. More than 50% children with serum sodium <125 mEq/L develop hyponatremic encephalopathy [10]. The majority of children reported with encephalopathy were otherwise healthy. They had received hypotonic fluids in the setting of SIAD; multiple deaths were reported [10, 56, 60].

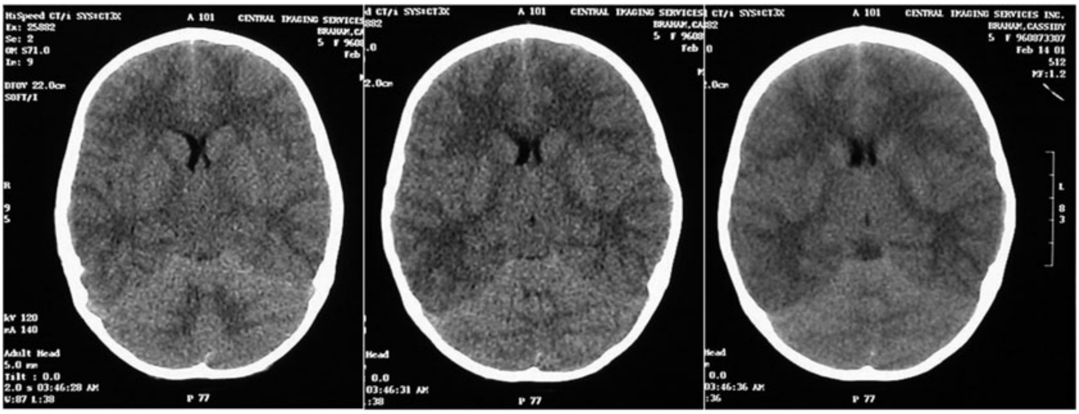

Fig. 3 Head CT demonstrating diffuse cerebral edema in a 5-year-old female who developed hyponatremic encephalopathy following a tympanoplasty. She was administered hypotonic maintenance fluids postoperatively and developed a serum sodium of 123 mEq/L

The primary symptoms of hyponatremia are those of cerebral edema, including headache, nausea, vomiting, and lethargy. Advanced symptoms of encephalopathy include seizures, coma, non-cardiogenic pulmonary edema, and decorticate posturing [56]. Cranial CT might not show mild cerebral edema, which is better detected by diffusion weighted imaging MRI [56, 61].

Treatment of Hyponatremic Encephalopathy

Hyponatremic encephalopathy is a medical emergency that requires immediate therapy with intravenous 3% sodium chloride (3% NaCl, 513 mEq/L) [62–64]. Fluid restriction, isotonic saline and vaptans have no role as initial therapy for hyponatremic encephalopathy as they are either ineffective, will not consistently increase the sodium by a sufficient degree, or do not have a rapid enough onset of action [65]. The consensus treatment for hyponatremic encephalopathy is to give repeated boluses of 3% NaCl (2 ml/kg, maximum 150 ml) in order to acutely raise the serum sodium by approximately 5 mEq/L (Table 2) [64]. This approach is indicated for both mild and severe symptoms and for acute and chronic hyponatremia. Hypertonic (3%) saline has proven to be safe and effective in treating hyponatremic encephalopathy in both children and adults [57, 66, 67]. The optimal magnitude of correction of hyponatremia is unknown. A correction of 10–20 mEq/L in the first 48 h is associated with best outcomes [59, 68, 69]. Treatment of hyponatremic encephalopathy should precede any neuroimaging studies to confirm cerebral edema and should occur in a monitored setting where the airway can be secured and serum sodium level measured frequently. Hypertonic saline can be given safely through a peripheral line in children and adults; a central line is not required for its administration.

Table 2 Treatment of symptomatic hyponatremia

1. 2 ml/kg bolus of 3% NaCl over 10 min. Maximum 150 ml
2. Repeat bolus 1–2 times as needed until symptoms improve. Goal: 5–6 mEql/L increase in serum sodium (SNa) in first 1–2 h
3. Recheck SNa following second or third bolus or Q 2 h
4. Hyponatremic encephalopathy is unlikely if no clinical improvement following an acute rise in serum sodium of 5–6 mEq/L
5. Stop further therapy with 3% NaCl boluses when patient is either:
(a) Symptom free: awake, alert, responding to commands, resolution of headache, and nausea
(b) Acute rise in sodium of 10 mEq/L in first 5 h
6. Correction in first 48 h should:
(a) Not exceed 15–20 mEq/L
(b) Avoid normo- or hypernatremia

Cerebral Demyelination Complicating the Correction of Hyponatremia

Cerebral demyelination is a rare complication following the correction of hyponatremia. Animal data has shown that correction of hyponatremia by greater than 20–25 mEq/L over 24 h can result in cerebral demyelination [68]. The condition is primarily seen in chronically hyponatremic patients of greater than 48-h duration with serum sodium <115 mEq/L. Other risk factors that increase the likelihood of the complication, independent of the degree of hyponatremia or magnitude of correction, are hypokalemia, thiazide diuretic use, severe liver disease, malnutrition, hypophosphatemia, and hypoxia [10]. Cerebral demyelination is not seen in patients with acute hyponatremia that is frequently encountered in children. In patients with severe and chronic hyponatremia, sodium should not be corrected by greater than 20 mEq/L in the first 48-h of therapy. Patients with hyponatremia due to water intoxication, diarrheal dehydration, or thiazide diuretics are at high risk for overcorrection of hyponatremia as they experience brisk free-water diuresis following volume expansion.

When symptomatic cerebral demyelination follows the correction of hyponatremia it typically follows a biphasic pattern. There is initial clinical improvement of the hyponatremic encephalopathy associated with correction of the serum sodium, which is followed by neurological deterioration 2–7 days later. Cerebral demyelination can be both pontine and extrapontine. Classic features of pontine demyelination include mutism, dysarthria, spastic quadriplegia, pseudobulbar palsy, a pseudocoma with a "locked-in stare," and ataxia. The clinical features of extrapontine lesions are more varied, including behavior changes and movement disorders. Radiographic features of cerebral demyelination typically lag behind the clinical symptoms. Cerebral demyelination is best diagnosed by MRI approximately 14 days following hyponatremia correction. The findings are symmetrical hypointense lesions on T1-weighted images and hyperintense lesions on T2-weighted images. Most patients demonstrate improvement in neurological symptoms and regression of radiographic findings.

Therapies for Hyponatremia

Hyponatremia is a multifactorial condition and its management depends on the underlying etiology. Fluid restriction is the cornerstone in the management of hyponatremia, as hyponatremia is unlikely to occur in the absence of fluid intake. Fluid restriction is indicated as part of the management of euvolemic and hypervolemic hyponatremia, as is seen in SIAD and congestive heart failure [70]. Fluid intake from all sources should be less than the daily urine output, and generally less than 600–1000 ml/day in an adult. However, this is a slow means of correcting hyponatremia and frequently ineffective.

Isotonic saline is primarily indicated for the management of hypovolemic hyponatremia as can occur with gastrointestinal losses, diuretics, or mineralocorticoid deficiency. Administering isotonic saline is useful in distinguishing hypovolemic hyponatremia from SIAD. Isotonic saline is generally ineffective in increasing the serum sodium in SIAD and can potentially worsen the hyponatremia [71]. An appreciable response in serum sodium in response to saline is consistent with volume depletion. Saline should be avoided in patients with hypervolemic hyponatremia as it can worsen fluid overload.

Studies are beginning to support the use or oral urea as practical therapy to correct asymptomatic chronic hyponatremia from SIAD [72]. Urea primarily works as an osmotic diuretic by increasing the renal solute load. A commercially available lemon-flavored urea powder drink (Ure-Na by Nephcentric LLC) is now available in the United States. In the United States it is medical food, Generally Regarded as Safe (GRAS) by the FDA, which can be purchased over the counter and used under medical supervision. It comes in 15 g single serve packets to be mixed in 3–4 ounces of water or juice. In can be used in conjunction with other therapies such as sodium chloride tablets. It is well tolerated and allows for a more liberal fluid restriction. Hypertonic saline is primarily indicated for the management of symptomatic hyponatremia, though in select cases it could be used to correct asymptomatic hyponatremia unresponsive to conventional therapies in patients with SIAD, cerebral salt wasting, and with loop diuretics in congestive heart failure.

Vasopressin-2 antagonists (vaptans) represent a relatively new class of medication for the management of SIAD. These agents antagonize the antidiuretic effect of AVP and results in a urinary free water diuresis (aquaresis) without increasing loss of electrolytes. Vaptans produce an aquaresis within 1–2 h of administration which abates within 12–24 h. When used to treat hyponatremia, vaptans result in an approximately 5–7 mEq/L increase in serum sodium within the first 24 h of administration, but the effect is variable [73]. The side effects of vaptans are increased thirst, polyuria, and dry mouth. Two vaptans are approved by the US FDA: tolvaptan for oral and conivaptan for intravenous use. Safety concerns with vaptans include elevation of alanine aminotransferase elevation and severe hepatotoxicity with long-term use, and serious overcorrection of hyponatremia has been reported. Overcorrection is of particular concern in neurologically impaired or critically ill children with restricted access to water. Vaptans are inhibitors of cytochrome P450 and should not be used in conjunction with other drugs known to be metabolized by this pathway. At present, vaptans cannot be recommended as a first-line agent in the management of SIADH, as they are expensive, not always necessary, and present safety concerns. Vaptans do appear to be a suitable second-line agent for short-term use in patients with SIAD after conservative measures have failed.

Hypernatremia

Hypernatremia is defined as serum sodium >145 mEq/L. The condition occurs in children and adults, often in the presence of restricted access to water for a variety of reasons. In most instances these patients are either debilitated by an acute or chronic illness or neurologic impairment or are at the extremes of age. Diarrheal dehydration is an important cause of hypernatremia, though is less common than previously reported, presumably due to the advent of low solute infant formulas, the increased use and availability of oral rehydration solutions, and better access to care. A group at high risk for developing hypernatremia in the outpatient setting are breastfed infants [74]. Hypernatremic dehydration results from a combination of insufficient lactation and high breast milk sodium concentration [75]. Contributing factors in the intensive care setting are excess sodium administration, renal concentrating defects, gastrointestinal fluid losses, increased insensible water losses, restricted access to oral fluids, and dialysis-related complications. Excess intake can occur via infusion of hypertonic solutions, blood products, and sodium bicarbonate. Increased insensible water losses occur with fever, tachypnea, and burns. Hypernatremia can result from intentional salt poisoning, in particular in children with gastrostomy tubes [76]. Serum sodium levels >145 mEq/L should be considered abnormal and evaluated in order to prevent the development of significant hypernatremia.

Pathogenesis

The body has two defenses to protect against developing hypernatremia: the ability to produce concentrated urine by reabsorbing filtered water and a powerful thirst mechanism. Antidiuretic hormone (ADH) release occurs when the plasma osmolality exceeds 275–280 mOsm/kg and results in a maximally concentrated urine when the plasma osmolality exceeds 290–295 mOsm/kg. Thirst is the second line of defense but provides the ultimate protection against hypernatremia. If this mechanism is intact and there is unrestricted access to free water, it is rare to develop sustained hypernatremia from either excess sodium ingestion or a renal concentrating defect.

Diagnosis

The cause of hypernatremia is usually multifactorial and a systematic approach is required to determine the underlying etiology (Fig. 4). Serum sodium, glucose, and osmolality must be simultaneously evaluated. Elevated serum sodium is always associated with hyperosmolality and should be considered abnormal. In association with significant hyperglycemia, the serum sodium concentration is depressed due to the associated translocation of fluids from the intracellular to extracellular space, and therefore true hypernatremia will be masked. Once the diagnosis of hypernatremia is established, a detailed history and review of fluid intake is obtained to determine if the patient has an intact thirst mechanism, had restricted access to fluids, or was not provided adequate free water in intravenous fluids.

The following should be evaluated: gastrointestinal losses, urinary output, dermal losses from fever or burns, diet history (including tube feedings), medication history (including diuretics), and sources of exogenous sodium. Urine volume should be measured and compared to fluid intake. Urine osmolality and electrolytes should be determined to assess if the renal concentrating ability is appropriate and to quantify urinary free water losses. Salt poisoning should be considered in cases of severe and unexplained hypernatremia. A gastric or stool sodium concentration higher than plasma sodium is virtually diagnostic of salt poisoning. Pseudohypernatremia is reported to occur with vecuronium and esmolol, due to interference with ion-selective electrodes [77].

Fig. 4 Diagnostic approach to hypernatremia

Diabetes Insipidus

Diabetes insipidus (DI) occurs due to either inadequate vasopressin production, termed central diabetes insipidus, or renal resistance to vasopressin, termed nephrogenic diabetes insipidus (NDI). NDI can be congenital or acquired, secondary to either: (i) resistance of AVP in the collecting tubule; (ii) impaired medullary countercurrent mechanism; and (iii) increased solute excretion by the kidney [78]. Acquired forms of NDI are commonly encountered in practice, but the congenital forms are the most severe. Hypernatremia is a presenting feature if there is an impaired access to water, such as during an acute illness or hospitalization.

Diabetes insipidus needs to be ruled out in two circumstances: (i) unexplained hypernatremia, and (ii) polyuria and polydipsia. Whenever a patient has hypernatremia (sodium >145 mEq/L) out of proportion to the history, evaluation of renal concentrating ability is indicated. Many patients who present with hypernatremia show a renal concentrating defect. Less than maximally concentrated urine (<800 mOsm/kg) in the face of hypernatremia associated with signs of dehydration is a sign of a renal concentrating defect, as hypernatremia is a maximal stimulus for ADH release.

Patients with hypernatremia should have a simultaneous measurement of plasma and urine osmolality. Urine osmolality that is less then maximally concentrated (<800 mOsm/kg) in the face of hypernatremia is evidence of a renal concentrating defect. Urine osmolality <300 mOsm/kg is consistent with DI and between 300 and 800 mOsm/kg is consistent with a partial renal concentrating defect. When hypernatremia is associated with a renal concentrating defect, estimation of plasma copeptin helps distinguish central from NDI [79]. Copeptin, the C-terminal segment of the pre-hormone for AVP, can be used as a surrogate marker of ADH as it is easier and more reliable to measure than AVP.

Clinical Manifestations

Hypernatremia results in an efflux of fluid from the intracellular space to the extracellular space to maintain osmotic equilibrium. This leads to transient cerebral dehydration with cell shrinkage. Brain cell volume can acutely decrease by as much as 10–15%, but then quickly adapts [80]. In response to extracellular hyperosmolarity, within 1 h brain cells significantly increase their intracellular content of sodium and potassium, amino acids, and unmeasured organic substances, called idiogenic osmoles. Within 1 week brain cells regain approximately 98% of their water content. If severe hypernatremia develops acutely, the brain may not be able to increase its intracellular solute sufficiently to preserve its volume, and the resulting cellular shrinkage can cause structural changes. Cerebral dehydration from hypernatremia can result in functional changes and a physical separation of the brain from the meninges leading to a rupture of the delicate bridging veins and extra-axial or intracerebral hemorrhages [81]. Venous sinus thrombosis leading to infarction can also develop. Acute hypernatremia has also been shown to cause cerebral demyelinating lesions in both animals and humans (Fig. 5) [82]. Patients with hepatic encephalopathy are at the highest risk for developing demyelinating lesions, especially if hypernatremia is a result of rapid overcorrection of preexisting hyponatremia [83].

Children with hypernatremia are usually agitated and irritable but can progress to lethargy, listlessness, and coma [84]. The degree of central nervous system depression correlates with the severity of hypernatremia. Neurologic examination shows increased tone, nuchal rigidity, and brisk reflexes. Myoclonus, asterixis, and chorea can be present; tonic-clonic and absence seizures have been described. Hyperglycemia is a particularly common consequence of hypernatremia in children. Severe hypernatremia can also result in rhabdomyolysis [85].

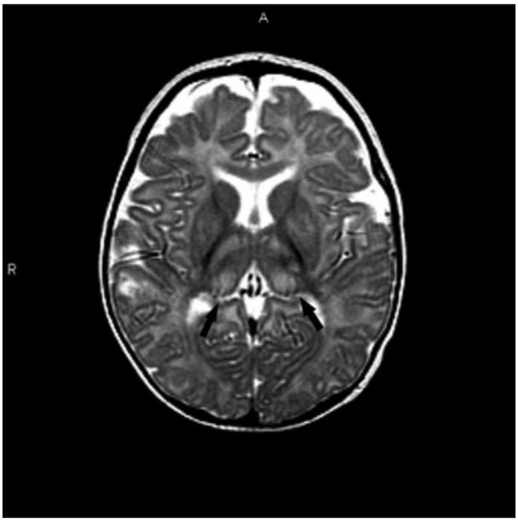

Fig. 5 Extrapontine myelinolysis on CT in a 5-month-old female who presented hypernatremia from central diabetes insipidus and a serum sodium of 195 mEq/L

Treatment

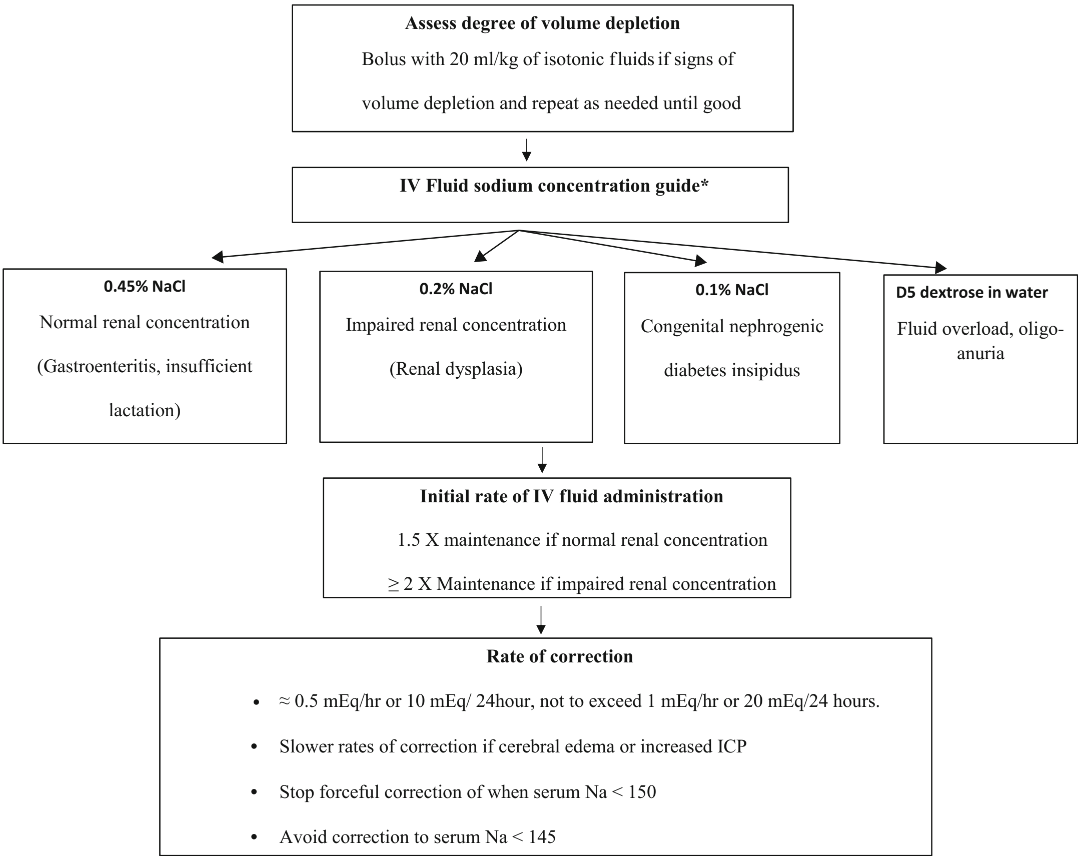
The cornerstone of hypernatremia management is providing adequate free water to correct the serum sodium concentration, but doing this at a rate that limits the risk of brain injury. Hypernatremia is frequently accompanied by volume depletion. If hemodynamic instability is present, fluid resuscitation with an isotonic solution should be instituted to establish normal hemodynamics prior to slowly correcting the free-water deficit (Fig. 6). Following initial volume expansion, the composition of parenteral fluid therapy largely depends on the etiology of the hypernatremia. Patients with sodium overload or a renal concentrating defect require a more hypotonic fluid than patients with volume depletion and intact renal concentrating ability. Oral hydration should be instituted as soon as it can be safely tolerated. Plasma electrolytes should be checked frequently until adequate correction is achieved.

A simple way of estimating the minimum amount of fluid necessary to correct the serum sodium is by the following equation:

$$\text{Free water deficit (ml)} = 4 \times \text{lean body weight (kg)} \times \text{desired change in serum sodium (mEq/l)}$$

Larger amounts of fluid are required depending on the fluid composition. To correct a 3 L free water deficit, approximately 4 L of 0.2% sodium chloride in water or 6 L of 0.45% sodium chloride in water would be required, as they contain approximately 75% and 50% free water, respectively. The calculated deficit does not account for insensible losses or ongoing urinary or gastrointestinal losses. Maintenance fluids, which include replacement of urine volume with hypotonic fluids, are given in addition to the deficit replacement. Glucose containing replacement fluids should be limited as they can result in significant hyperglycemia.

The rate of correction of hypernatremia is largely dependent on the severity of the hypernatremia and the etiology. Due to the brain's relative inability to extrude unmeasured organic substances (idiogenic osmoles), rapid correction



Assess degree of volume depletion
Bolus with 20 ml/kg of isotonic fluids if signs of volume depletion and repeat as needed until good
IV Fluid sodium concentration guide*
0.45% NaCl
Normal renal concentration
(Gastroenteritis, insufficient lactation)
0.2% NaCl
Impaired renal concentration
(Renal dysplasia)
0.1% NaCl
Congenital nephrogenic diabetes insipidus
D5 dextrose in water
Fluid overload, oligo-anuria
Initial rate of IV fluid administration
1.5 X maintenance if normal renal concentration
≥ 2 X Maintenance if impaired renal concentration
Rate of correction
≈ 0.5 mEq/hr or 10 mEq/ 24hour, not to exceed 1 mEq/hr or 20 mEq/24 hours.
Slower rates of correction if cerebral edema or increased ICP
Stop forceful correction of when serum Na < 150
Avoid correction to serum Na < 145

Fig. 6 Management of hypernatremia

of hypernatremia can lead to cerebral edema. While there are no definitive studies that document the optimal rate of correction without developing cerebral edema, correction at a rate not exceeding 1 mEq/h or 15 mEq/24 h is reasonable. In severe hypernatremia (>170 mEq/L), serum sodium should not be corrected to below 150 mEq/L in the first 48–72 h [86]. If the patient is at high risk for developing cerebral edema, such as with head trauma or encephalitis, the rate of correction of hypernatremia should be slower.

It may not be possible to correct hypernatremia with free water alone in patients with severe kidney injury, fluid overload with left ventricular failure, or in cases of severe salt poisoning. When hypernatremia cannot be managed with free water supplementation alone, dialysis may be required [87]. Dialytic therapies provide an option to correct both fluid and electrolyte disorders simultaneously [88].

Seizures occurring during the correction of hypernatremia are not uncommon in children and may be a sign of cerebral edema [89]. Hypotonic fluid infusion should be ceased, and hypertonic saline should be administered when cerebral edema is suspected during the correction of hypernatremia. The presence of signs of intracranial hypertension, such as headache, hypertension, bradycardia, abnormal respiratory pattern, and coma warrants rapid treatment including securing the airway, administration of hypertonic saline, and hyperventilation if herniation seems imminent. In symptomatic children, assessment of progressive cerebral edema by CT head is indicated. Seizures not associated with concomitant cerebral swelling are usually self-limited and not a sign of long-term neurologic sequelae.

Abstract

Potassium, the most abundant intracellular cation, plays a key role in vital cell functions. To ensure somatic growth, children maintain a positive potassium balance. Total body potassium content depends on both dietary intake and its excretion, primarily through the kidneys. The plasma concentration of potassium is a function of the total body potassium content and the internal potassium balance, determined by the relative distribution of potassium between the extracellular and intracellular fluid compartments. Insulin, catecholamines, and acid-base balance play a major role regulating the internal potassium balance. The renal handling of potassium is a complex process that involves filtration, reabsorption, and secretion. These processes are developmentally regulated; thus, the evaluation of children with disorders in potassium balance should always take into consideration the developmental stage of the patient. Hyperkalemia and hypokalemia are common and potentially life-threatening disorders. A careful history, including dietary intake, use of drugs with an effect on potassium metabolism, and evaluation of acid-base balance, is essential to establish an accurate diagnosis. In addition, identifying the cause requires a meticulous assessment of renal excretion of potassium, including estimation of GFR, evaluation of proximal tubular function, and the activity of mineralocorticoids in the distal nephron. The

treatment should be aimed at correcting the primary cause, when possible. In symptomatic patients, the disturbances in plasma potassium concentration should be corrected promptly, with close monitoring of the electrocardiogram (ECG).

Keywords

Potassium homeostasis · Internal potassium balance · External potassium balance · Hyperkalemia · Hypokalemia

Almost all body content (98%) of potassium is located within cells, where it plays a key role in DNA and protein synthesis, cell growth, and regulating cell volume [1]. The remaining 2% of total body potassium resides in the extracellular fluid, where its concentration is tightly regulated within a narrow range (3.5–5.0 mEq/L in the adult). The internal distribution of potassium between the intra- and extracellular compartments and the external balance between intake and excretion, by the kidney and GI tract, are tightly regulated by multiple complex and efficient mechanisms.

Potassium Homeostasis

Total body potassium content depends on the balance between dietary intake and excretion. In the adult, most (~90%) of the potassium consumed on a daily basis is excreted by the kidney, with only 10% excreted in the feces [2]. A healthy adult maintains a zero potassium balance. Approximately 85% of ingested potassium is reabsorbed by the gut in the adult [3].

Total body potassium content increases from birth to adulthood, with the fastest rate of accumulation during infancy. The increase in total body potassium content correlates with an increase in cell number and potassium concentration with advancing age. Early in life, a positive potassium balance is necessary to ensure somatic growth [4]. This is reflected, in part, in the higher plasma potassium values observed in infants, particularly in preterm neonates [5].

Regulation of Internal Potassium Balance

The regulation of potassium distribution between the intracellular and extracellular compartments is referred to as internal potassium balance. In the adult, the daily dietary intake of potassium of ~1 mEq/kg approaches or exceeds the total potassium present within the extracellular fluid space. This potassium load must be excreted. However, only 50% of an oral or intravenous load of potassium is excreted during the first 4–6 h after its administration [6]. Life-threatening hyperkalemia does not occur because approximately 80% of the absorbed potassium is rapidly translocated from the extracellular space into the intracellular compartment [7]. The buffering capacity of the combined cellular storage reservoirs is capable of sequestering up to approximately 3500 mEq of potassium, which is massive compared with the extracellular pool [2].

To maintain a steep potassium concentration gradient across cell membranes, the body uses a significant amount of energy, provided by the ubiquitous Na-K-ATPase which transports three sodium ions out of and two potassium ions into the cell at the expense of the hydrolysis of adenosine triphosphate (ATP). This unequal cation exchange ratio produces a charge imbalance across the cell membrane, and thus the Na-K-ATPase is defined as an electrogenic pump. Positively charged potassium ions, highly concentrated within the cell, passively leak out of cells down a concentration gradient through ubiquitously expressed potassium-selective channels. A steady state is reached at which the outward movement of positively charged potassium is opposed by the negative cell potential. At this cell equilibrium potential, the net transmembrane flux of potassium is zero.

Regulation of internal potassium balance in the neonate is influenced by developmental stage-specific expression of potassium transporters, including the Na-K-ATPase, as well as channels, receptors, and signal transduction pathways [8, 9]. Thirty to fifty percent of very low-birth weight (birth weight lower than 1500 g) or very preterm (less than 28 weeks postmenstrual age) infants develop nonoliguric hyperkalemia. This is defined as a plasma potassium concentration higher than 6.5 mEq/L within the first 72 hours of life in the presence of normal renal function for age, and normal urine output (>1 ml/kg/h) [10–13]. Although the pathophysiology is not completely understood, it has been proposed that it is the result of immaturity of the mechanisms that regulate internal distribution of potassium, including low rates of Na-K pump activity as well as a limited secretory capacity of the kidney for potassium [11, 12, 14]. Prenatal steroid treatment may prevent nonoliguric hyperkalemia via induction of Na-K-ATPase activity in the fetus [15].

The chemical, physical, and hormonal factors that acutely influence the internal balance of potassium are listed in Table 1 and are discussed below. Potassium uptake into cells is acutely stimulated by insulin, β2-adrenergic agonists, and alkalosis and is blocked by α-adrenergic agonists, acidosis, and hyperosmolality.

Plasma Potassium Concentration

An increase in extracellular potassium concentration favors potassium movement into the cell by the Na-K-ATPase. The concentration of potassium in the extracellular compartment can increase without change in total body potassium content in response to endogenous release of potassium during tissue breakdown (intravascular hemolysis, rhabdomyolysis, and tumor lysis syndrome) and severe exercise, the latter mediated by ATP depletion and opening of ATP-dependent potassium channels.

Table 1 Factors that regulate *internal* potassium balance

Factors	Effect on cell uptake of potassium
Physiologic factors	
Plasma K concentration	
Increase	Increase
Decrease	Decrease
Insulin	Increase
Catecholamines	
α-Agonists	Decrease
β-Agonists	Increase
Pathologic factors	
Acid-base balance	
Acidosis	Decrease
Alkalosis	Increase
Hyperosmolality	Enhances cell efflux
Cell breakdown	Enhances cell efflux

Hormones

Insulin, the most important hormonal regulator of internal potassium balance, stimulates potassium cellular uptake by enhancing Na-K-ATPase activity in the liver, skeletal muscle, adipocytes, and brain. This is independent of its effects on glucose metabolism [16]. Maintenance of fasting plasma potassium concentration within the normal range requires basal insulin secretion [17]. In adults, an increase in plasma potassium greater than 1.0 mEq/L results in a significant increase in peripheral insulin levels, yet a more modest elevation of approximately 0.5 mEq/L has no effect [17–19]. In diabetes, characterized by insulin deficiency, there is a reduction in uptake of potassium by muscle and liver [7].

Catecholamines enhance the cell uptake of potassium via stimulation of Na-K-ATPase activity in skeletal muscle and hepatocytes through β2- adrenergic receptors [20]. The effect of epinephrine on potassium balance in the adult is biphasic and is characterized by an initial increase, followed by a prolonged fall in plasma potassium concentration to a final value below baseline. The initial transient rise in plasma potassium results from α-adrenergic receptor stimulation which causes release of potassium from hepatocytes and impairs cell uptake of potassium [20–23]. β2-receptors stimulate the Na-K pump and thus promote enhanced uptake of potassium by skeletal and cardiac muscle, effects that are inhibited by nonselective β-blockers including propranolol and labetalol [20, 23–27]. The effects of these hormones on the internal potassium balance have been exploited extensively in the treatment of hyperkalemia (Fig. 1 [28]).

Triiodothyronine (T3) promotes Na-K-ATPase-mediated potassium cellular uptake in skeletal muscle [29] primarily as a transcriptional activator of target genes. In addition, there is a nontranscriptional mechanism involving translocation

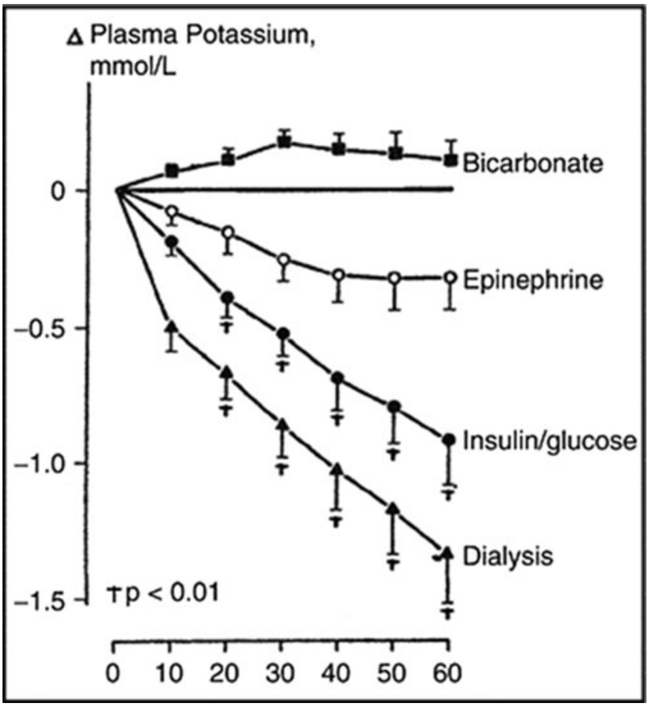

Fig. 1 Changes in plasma potassium concentration (mmol/L) during intravenous infusion of bicarbonate (8.4%), epinephrine, or insulin in glucose and during hemodialysis in adult patients on maintenance hemodialysis (From Blumberg et al., 28)

of Na-K-ATPase to the plasma membrane [30, 31]. The increase in Na-K-ATPase activity in kidney, brain, and lung observed after birth is dependent on normal thyroid status [32].

Acid-Base Balance

Acid-base balance has a direct effect on the internal potassium distribution [33]. While acidemia increases the plasma concentration of potassium by stimulating its exit from the cell, alkalemia stimulates potassium into cells, leading to a decrease in plasma potassium concentration. However, the reciprocal changes in plasma potassium that accompany acute changes in blood pH differ widely among the four major acid-base disorders; metabolic disorders cause greater disturbances in plasma potassium than do those of respiratory origin, and acute changes in pH result in larger changes in plasma potassium than do chronic conditions [34].

Acute metabolic acidosis after administration of an inorganic mineral acid such as hydrochloric acid, which contains an anion (chloride) that does not enter the cells, increases the concentration of potassium in plasma. In this case, the protons of the acid freely enter the cell, where they are neutralized by intracellular buffers, while the impermeant anion stays in the extracellular compartment. To maintain electroneutrality, potassium ions are extruded from the cells. Conversely, if the acidemia is induced by acute organic anion acidosis (lactic acid or acetoacetic acid), there is no change in plasma potassium since the anion of the acid readily enters the cell with the proton, maintaining electroneutrality without the need of potassium to leave the cell [34–36].

In respiratory acid-base disturbances, in which carbon dioxide and carbonic acid readily permeate cell membranes, little transcellular shift of potassium occurs [34]. By contrast, changes in plasma bicarbonate concentration lead to changes in plasma potassium concentration in the opposite direction, independent of the effect on intracellular pH [37]. This explains why during acute respiratory acidosis, a condition characterized by acidemia with an elevated serum bicarbonate, there is minimal increase in plasma potassium, while during acute metabolic acidosis, characterized by acidemia but with a low serum bicarbonate concentration, the increase in plasma potassium concentration is more significant.

Other Factors

A number of other pathologic conditions alter the internal potassium balance. An increase in plasma osmolality causes water to shift out of cells. The consequent increase in intracellular potassium concentration augments the transcellular concentration gradient, favoring its movement to the extracellular compartment. This represents an additional risk in the hyperglycemic diabetic patients, in whom the absence of insulin exacerbates hyperkalemia.

Succinylcholine, a depolarizing paralytic agent and an agonist of nicotinic acetylcholine receptors, which are found predominantly in skeletal myocyte membranes, may lead to efflux of potassium from myocytes into the extracellular fluid under certain pathologic states, including states characterized by upper or lower motor neuron denervation, immobilization, infection, muscle trauma or inflammation, and burn injury [38, 39].

Finally, parenteral administration of cationic amino acids such as lysine, arginine, or epsilon-aminocaproic acid may lead to electroneutral exchange of cell potassium for the cationic amino acid in skeletal myocytes and thus hyperkalemia [40–42].

Regulation of External Potassium Balance

Renal Handling of Potassium

The kidneys are responsible for approximately 90% of potassium excretion. To maintain homeostasis, the goal of the adult, potassium intake should equal excretion. However, the renal response to changes in potassium intake is slow. An increase in dietary potassium intake is matched by a parallel increase in renal potassium excretion within hours, yet maximal rates of potassium excretion are not attained for several days.

Children and adults ingesting an average American diet that contains sodium in excess of potassium excrete urine with a sodium-to-potassium ratio greater than one [43, 44]. Although breast milk and commercially available infant formulas generally provide a sodium-to-potassium ratio of approximately 0.5–0.6, the urinary sodium-to-potassium ratio in the newborn up to 4 months of age generally exceeds 1 and even 2 in newborns <34 weeks of gestational age. This may reflect the greater requirement of potassium over sodium for growth and suggests a relative hyporesponsiveness of the neonatal kidney to mineralocorticoid activity.

The renal handling of potassium is a complex process that involves filtration, reabsorption, and secretion. Plasma potassium is freely filtered at the glomerulus. In the mature kidney, the proximal tubule reabsorbs 60–70% of filtered potassium along with sodium, chloride, and fluid. An additional 25% of filtered potassium is reabsorbed in the thick ascending limb of the loop of Henle, and bidirectional transport (secretion and reabsorption) in the distal nephron [2, 45].

In newborns, potassium clearance is low, even after correction for their low GFR [5, 43, 46]. Infants, like adults, can excrete potassium at a rate that exceeds its GFR, reflecting the capacity for net tubular secretion. However, they are unable to excrete an exogenously administered potassium load as efficiently as the adult [47]. Comparison of the fractional delivery of potassium to the early distal tubule with that present in the final urine reveals that the distal nephron of the young (2-week-old) rat secretes approximately fivefold less potassium than the older (5-week-old) rat [48]. Similarly, clearance studies in saline-expanded dogs also provide indirect evidence of a diminished secretory and enhanced reabsorptive capacity of the distal nephron to potassium early in life [49]. In general, the limited potassium secretory capacity of the immature kidney becomes clinically relevant only under conditions of potassium excess.

Glomerular Filtration

The first step in renal potassium excretion involves filtration through the glomerulus. In adults and older children with CKD, once the GFR is below 25 ml/min/1.73m^2, hyperkalemia may develop due to limited potassium filtration. Almost all premature infants have a GFR lower than 25 ml/min/1.73m^2 during the first week of life, representing a limiting factor for renal potassium excretion.

Proximal Tubule

The concentration of potassium entering the proximal convoluted tubule (PCT) is similar to that of plasma. In mature kidneys, 60–70% of filtered potassium is reabsorbed in the PCT, similar to the absorption rate of sodium and water (Fig. 2) [50–52]. This is not different from the filtered load of potassium (50–60%) reabsorbed along the proximal tubules of suckling (13–15-day-old) rats [48, 53].

Reabsorption of potassium along the early proximal tubule is passive, closely following that of sodium and water [54], and has been proposed to occur by solvent drag, driven by active sodium absorption, and diffusion via the paracellular pathway [55–57]. Potassium diffusion is driven by the lumen-positive transepithelial voltage in the second half of the proximal tubule and the slightly elevated concentrations of potassium in the lumen [58].

In the proximal tubule, as in all other nephron segments discussed below, transepithelial sodium reabsorption requires the coordinated function of apical sodium transporters and the basolateral Na-K-ATPase which actively extrudes sodium from the cell into the interstitium. This maintains a low intracellular sodium concentration, which favors apical sodium entry. Most of the regulation of potassium reabsorption along the proximal tubule can be accounted for by alterations in sodium transport.

Electrogenic sodium-coupled entry of substrates across the luminal cell membrane of the proximal tubule as well as bicarbonate exit across the basolateral cell membrane is driven by the potential differences across the respective cell membranes, which are maintained by potassium flux through potassium channels [59].

Thick Ascending Limb of the Loop of Henle (TALH)

The mature loop of Henle absorbs 25% of filtered potassium through both transcellular and paracellular pathways. The ubiquitous Na-K-ATPase

Fig. 2 Potassium transport along the nephron. (**a**) The percentages of filtered potassium reabsorbed along the proximal tubule and thick ascending limb of the loop of Henle (TALH) are indicated for the adult (A). Arrows show direction of net potassium transport (reabsorption or secretion). GFR glomerular filtration rate. (**b**) Simplified cell models of potassium transport along the nephron, showing apical transporters unique to discrete nephron segments and cells therein and basolateral transporters which are similar in all nephron segments (From [52])

present in the basolateral membrane maintains a low intracellular sodium concentration which provides the driving force for the apical Na-K-2Cl cotransporter (NKCC2) that translocates a single potassium ion into the cell accompanied by one sodium and two chloride ions (Fig. 2). The diuretics furosemide and bumetanide specifically inhibit NKCC2 and thus block sodium, potassium, and chloride reabsorption at this site.

A high intracellular potassium concentration promotes recycling of some of the absorbed potassium into the lumen via an apical low-conductance potassium channel, known as the renal outer medullary potassium channel (ROMK) since it was originally identified in the thick ascending limb of the rat outer medulla [60–62]. This provides a continuous supply of potassium ions required for the NKCC2 and generates a positive luminal voltage that drives potassium absorption through paracellular pathways, as well as calcium and magnesium. The intracellular potassium leaves the cell through the basolateral membrane, primarily cotransported with chloride or via a potassium channel.

The immature distal nephron receives up to 35% of the potassium-filtered load, in contrast to 15–20% in the adult kidney [48], suggesting that the TALH undergoes a significant postnatal increase in its capacity for reabsorption. This is supported by studies in rats showing a significant increase in the fractional reabsorption of potassium along the TALH, expressed as a percentage of delivered load, between the second and sixth weeks of postnatal life [48].

The mRNA expression of NKCC2 in mice is developmentally regulated. During the early embryonic stage, the signal is undetectable. Expression is first observed in the metanephros by day 14.5 postconception and continues to increase progressively through late gestation. By the end of the first week of postnatal life, the mRNA expression is stronger [63]. In rat kidney, the mRNA encoding NKCC2, absent at birth, is first expressed on postnatal day 8, coincident with completion of nephrogenesis [9]. It increases, at least in medulla, between postnatal days 10 and 40 [64]. Na-K-ATPase activity in the TALH of the neonatal rabbit is only 20% of that measured in the adult when expressed per unit of dry weight [65]. The postnatal increase in pump activity is associated with a parallel increase in expression of medullary Na-K-ATPase mRNA [64].

Distal Nephron

Within the aldosterone-sensitive distal nephron (ASDN) of the fully differentiated kidney, the late distal convoluted tubule (DCT), connecting tubule (CNT), and cortical collecting duct (CCD) are considered to be the primary sites of potassium secretion, which can approach 20% of the filtered load [50, 66–68] (Fig. 2). The DCT secretes a constant small amount of potassium into the urinary fluid [69]. An elevation in plasma potassium concentration inhibits the thiazide-sensitive NaCl cotransporter NCC expressed at the apical membrane of the DCT. The basolateral potassium channel Kir4.1/Kir5.1 acts as a potassium sensor; high potassium intake inhibits Kir4.1/Kir5.1, which leads to inhibition of NCC via the chloride-sensitive WNK pathway [70–72]. This results in increased delivery of sodium into the CD stimulating potassium secretion in this segment. This observation may account for the ability of high potassium diets to lower blood pressure, in a fashion similar to that of thiazide administration [73].

Regulated bidirectional potassium transport occurs in the CNT and CCD, comprised of two major populations of cells. In general, CNT/principal cells reabsorb sodium and secrete potassium, whereas intercalated cells regulate acid-base balance but can reabsorb potassium in response to dietary potassium restriction or metabolic acidosis (Fig. 2) [74, 75]. Thus, the direction and magnitude of net potassium transport in these segments depend on the metabolic needs of the organism and reflect the balance of potassium secretion and absorption.

Potassium Secretion

Potassium secretion in the distal nephron is critically dependent on the reabsorption of sodium delivered to these segments. In the principal cells, sodium is absorbed via the luminal epithelial Na channel (ENaC) and then diffuses into the interstitium via the basolateral Na-K-ATPase (Fig. 2). The removal of the positive charge (Na+) from the lumen and accumulation of potassium within the cell creates a favorable electrochemical gradient for potassium secretion through apical potassium-selective channels. Basolateral potassium channels in these cells provide a route for intracellular potassium ions to recycle back into the interstitium, thereby maintaining the efficiency of the Na-K pump. Any factor that increases the electrochemical gradient across the apical membrane or increases the apical potassium permeability will promote potassium secretion. An apical electroneutral potassium chloride cotransporter has also been functionally identified in the CCD [76, 77].

Two major apical potassium-selective channels have been identified in the distal nephron: the small-conductance secretory potassium (SK) channel and the high-conductance BK channel [78].

The SK channel, restricted to the CNT/principal cell, mediates baseline constitutive potassium secretion [79, 80]. ROMK is considered to constitute the SK channel since there is absence of SK channel activity in apical membranes from both TALH and collecting duct in ROMK null mice [81].

The BK channel intercalated cells is considered to mediate flow-stimulated potassium secretion [82, 83]. The BK channel, rarely open at the physiologic conditions, can be activated by cell depolarization, membrane stretch, and increases in intracellular calcium ion concentration elicited by increases in urinary flow rate [84–87]. The role of the BK channel in flow-stimulated urinary potassium secretion has been confirmed in mouse models [88, 89]. The BK channel assumes great importance in regulating potassium homeostasis under conditions where SK/ROMK channel-mediated potassium secretion is limited.

The “with-no-lysine” kinases, or WNK kinases, comprise a family of serine/threonine kinases uniquely characterized by anomalous placement of the catalytic lysine crucial for binding to ATP. They act as molecular switches that direct differential effects on downstream ion channels, transporters, and have an essential role in sodium and potassium regulation [90]. WNKs phosphorylate and thereby activate the thiazide-sensitive NCC [91]. WNK1, WNK3, and WNK4 are all expressed in the kidney. Intracellular chloride concentration plays a major role modulating WNK activity: Chloride binds to the catalytic domain of WNKs, blocking its autophosphorylation and kinase activity. However, WNK kinases are chloride but not potassium sensitive. It seems that the regulation of NCC by potassium involves modulation of intracellular chloride concentration [92]. Kir4.1 regulates NCC expression by the modulation of the Cl−sensitive with-no-lysine kinase–SPAK pathway.

Potassium Absorption

In conditions of potassium depletion or metabolic acidosis, the distal nephron may become a potassium-absorbing segment. Potassium is actively absorbed in exchange for protons through the H-K-ATPase, localized to the apical membrane of alpha intercalated cells [74, 93–95]. Two isoforms of the H-K-ATPase are found in the kidney: The gastric isoform, HKAg, is normally found in gastric parietal cells and is responsible for acid secretion into the lumen whereas the colonic HKAc isoform is a structurally related H-K-ATPase found in distal colon that mediates active potassium reabsorption [94]. Expression of the apical gastric-like H-K-ATPase in the rat and rabbit intercalated cell is increased in response to dietary potassium restriction and metabolic acidosis [74, 93, 96, 97]. A reduction in potassium intake leads to a fall in potassium secretion by the distal nephron within 5–7 days in rat [98]. This adaptation is associated with a decrease in the number of apical SK/ROMK [99] and BK [100] channels and stimulation of H-K-ATPase-mediated potassium reabsorption in intercalated cells in the distal nephron [101]. Stimulation of luminal H-K-ATPase activity in intercalated cells results not only in potassium retention but also in urinary acidification and metabolic alkalosis.

Developmental Regulation of Distal Potassium Transport

Potassium secretion measured in isolated microperfused CCD from neonatal rabbits at physiological flow rates is absent at birth. It first becomes evident at 4 weeks of age and increases abruptly after that, reaching maturity by 6 weeks of age [68]. Patch clamp analysis in maturing rabbit CCD showed a clear developmental increase in

ROMK channel activity between 2 and 5 weeks of age, consistent with data from isolated perfused CCDs at low flow rates. This suggests that the appearance of baseline potassium secretion in the CCD is the result of the development of SK/ROMK channels [102]. Flow-stimulated potassium secretion in the rabbit appears by 5 weeks of postnatal life, parallel with the appearance of BK channel expression.

Renal Response to Dietary Potassium

It has been shown that changes in dietary potassium can induce kaliuresis before an increase in plasma potassium level or a change in aldosterone concentration is detectable. This data suggests a gut-sensing mechanism that directly stimulates renal potassium excretion, not mediated by aldosterone [99]. After ingestion of a potassium-containing meal, an increase in the potassium concentration in the splanchnic circulation stimulates local sensors that can directly induce a kaliuretic response. This process, known as the feed forward mechanism, does not require an increase in plasma potassium concentration and is not regulated by aldosterone (205). Evidence for a potassium sensor in the hepatorenal system arises from experiments showing that an infusion of KCl directly into the hepatoportal circulation increases urinary potassium excretion in the absence of any elevation in plasma potassium. This effect is abolished by bumetanide, suggesting the presence of an isoform of the Na-K-2Cl cotransporter, NKCC1, in the hepatoportal system that mediates a signal transmission to the kidneys with consequent kaliuresis [103, 104]. The inverse is observed during conditions of chronic dietary potassium restriction. Before hypokalemia develops, the renal excretion of potassium is reduced, probably mediated by sensors in the gastric or hepatoportal circulation that in some way inactivates ROMK [105].

Hormones

Aldosterone stimulates sodium reabsorption and potassium secretion in principal cells of the fully differentiated ASDN [106, 107]. Among the cellular and molecular effects of an increase in circulating levels of aldosterone are increases in density of ENaC channels, achieved by the recruitment to and retention of intracellular channels at the apical membrane, de novo synthesis of ENaC subunits, and activation of preexistent channels, as well as stimulation of Na-K-ATPase activity by translocation of preformed transporters to the membrane and translation of new sodium pump subunits [108–113].

Plasma aldosterone concentrations in premature infants and newborns are higher than those measured in the adult [43, 114]. Yet, clearance studies in fetal and newborn animals demonstrate a relative insensitivity of the immature kidney to the hormone [43, 115] [43, 115–117]. The density of aldosterone binding sites, receptor affinity, and degree of nuclear binding of hormone receptor are believed to be similar in mature and immature rats [115].

Circadian Control of Renal Potassium Excretion

Renal potassium excretion varies during the 24-h day in the adult [118, 119]. Although some of this variation can be attributed to timing of meals, a pattern of low rates of potassium excretion at night and in the morning and high rates in the afternoon is evident, independent of feeding, drinking, and activity [118, 119]. The distal nephron expresses core clock genes such as period circadian regulator 1 gene (PER1), a protein coding gene that is part of the clock gene network. ENaC, aquaporin 2, and vasopressin receptors have marked circadian rhythms, which could influence indirectly the excretion of potassium [120, 121]. Moreover, recent data from space flight simulation suggest that there is also an infradian rhythmicity to aldosterone secretion [122]. It is unknown whether a circadian cycle of urinary potassium excretion prevails in infancy.

Contribution of the Gastrointestinal Tract

Up to 90% of the dietary potassium is absorbed in the gastrointestinal tract. The colon is considered to be the main target for regulation of intestinal potassium excretion [123]. Potassium transport in the colon represents the balance of secretion and absorption [124]. Under baseline conditions, net potassium secretion predominates over absorption in the adult, whereas the neonatal gut is poised for net potassium absorption [123].

Potassium secretion requires potassium uptake by the Na-K-ATPase and NKCC located in the basolateral membrane of colonocytes; potassium is then secreted across the apical membrane through potassium channels, including a calcium-activated BK channel similar to that found in the distal nephron [125–129]. Potassium absorption is mediated by two H-K-ATPases localized to the apical membrane of the distal colon [130].

Stool potassium content can be enhanced by any factor that increases colonic secretion, including aldosterone, epinephrine, and prostaglandins [7, 131, 132]. Indomethacin and dietary potassium restriction reduce potassium secretion by inhibiting the basolateral transporters and apical potassium channels. Diarrheal illnesses are typically associated with hypokalemia, presumably due to the presence of nonreabsorbed anions, an enhanced electro-chemical gradient established by active chloride secretion, and secondary hyperaldosteronism due to volume contraction [133].

Potassium adaptation in the colon is demonstrated by increased fecal potassium secretion after potassium loading and in the face of renal insufficiency. Fecal potassium excretion may increase substantially to account for 30–50% of potassium excretion in patients with severe chronic kidney disease [7, 134–136]. The enhanced colonic potassium secretion characteristic of renal failure requires induction and/or activation of apical BK channels in surface colonic epithelial cells [137].

Experimental data demonstrate that the immature intestine absorbs potassium more avidly than the adult. Intestinal potassium absorption measured after intragastric administration of KCl is higher in infant than in adult rats. In addition, rates of total cumulative Rb uptake – a marker of potassium transport – are higher in isolated distal colons from infant rats, suggesting increased potassium absorption in the distal colon of immature animals [138]. The higher rates of intestinal potassium absorption in infant animals are the consequence of lower activity of the basolateral Na-K-ATPase and increased activity of apical potassium-absorptive pumps, such as H-K-ATPase and ouabain-sensitive Na-independent K-ATPase. This results in lower intracellular potassium concentration promoting net intestinal absorption in the neonate, in contrast to net secretion in the adult colon. This will contribute to a state of total body potassium retention and higher extracellular concentration in the neonatal period [123, 127, 139].

Disorders in Potassium Balance

Hyperkalemia

Hyperkalemia is a common and potentially life-threatening electrolyte disorder, defined as a plasma potassium concentration higher than 5 mEq/L in the adult. Before the diagnosis of hyperkalemia is established, pseudohyperkalemia, which results from release of intracellular potassium during phlebotomy or specimen processing, must be ruled out. Most laboratories will alert a healthcare provider as to the presence of hemolysis. However, in most instances, assessment of the degree of hemolysis in a blood sample is subjective, based on visual inspection of the color of the plasma. Therefore, as a general rule, all samples obtained by a heel stick, from fingertip or after prolonged use of tourniquet that show an elevated potassium level, should be considered a hemolyzed sample and must not be used to make therapeutic decisions.

Altered Internal Balance

Hyperkalemia due to an altered internal balance should be suspected if there are suggestive factors, such as metabolic acidosis and/or poorly controlled diabetes mellitus (see Table 1). Treatment in these cases should focus on correcting the underlying abnormality.

Altered External Balance

Hyperkalemia due to an altered external balance may be due to excessive potassium intake, impaired renal potassium secretion, or a combination of both. With normal kidney function, even a very high potassium intake should not lead to hyperkalemia, due to the rapid translocation of potassium into cells, unless administered as an acute bolus [140].

Commonly used tools to assess renal potassium secretion include the fractional excretion of potassium (FEK), the ratio of urinary potassium to sodium, and the transtubular potassium gradient (TTKG). The TTKG provides an indirect measure of the mineralocorticoid activity in the ASDN and is calculated using the equation:

$$\mathrm{TTKG} = \frac{(\mathrm{Urine}\ [K])/(\mathrm{Plasma}\ [K])}{(\mathrm{Urine\ Osmolality})/(\mathrm{Plasma\ Osmolality})}$$

where [K] equals the potassium concentration in mEq/L [141–143]. Measurements of TTKG have been reported to be lower in 27- than 30-week gestational age preterm infants followed over the first 5 weeks of postnatal life [144]. A TTKG value of 4.1 corresponded to the 3rd percentile for TTKG results and 13.1 to the 97th percentile [144]. Accordingly, in hyperkalemia, a TTKG value below 4.1 would be inappropriate and indicate low mineralocorticoid activity, suggesting impaired renal potassium secretion. Conversely, a TTKG value above 13.1 is consistent with high mineralocorticoid activity and would thus suggest excessive potassium intake as the underlying etiology of the hyperkalemia. However, although TTKG may be useful in the evaluation of children with potassium disturbances, during recent years several pitfalls have been identified. In states where the rate of excretion of urea deviates appreciably from normal, TTKG may overestimate the true renal K excretion. In addition, adequate urine sodium concentration (> 25 mEq/L) and a urine that is hypertonic compared to plasma are required to be able to use TTKG (303, 304). In preterm neonates, TTKG is low during the early neonatal period and does not correlate with plasma aldosterone levels, consistent with the low-tubular K excretion and mineralocorticoid resistance. This finding is probably physiologic or related to the presence of associated medical conditions such as the use of mechanical ventilation [145]. Therefore, TTKG should not be used in premature infants as the interpretation of this test is troublesome since developmental stage-specific limitations in renal potassium handling and urine concentration may confound the results.

In the neonatal period, hyperkalemia is defined as a plasma potassium concentration > 6 mEq/L in full-term neonates and of >6.5 mEq/L in premature infants. In very premature infants (postmenopausal age < 32 weeks), normal plasma potassium concentration could be up to 6.7 mEq/L during the 1st week of life [11, 146].

Causes of Hyperkalemia

The most common causes of hyperkalemia in infants and children are shown in Table 2. Neonates are more susceptible to effects of some medications, which can limit the already compromised Na-K-ATPase activity, the ability to shift K^+ into the cell, and the tubular response to mineralocorticoids. These include succinylcholine, digoxin overdose, and β2 adrenergic blockers causing an efflux of potassium from the cell and inhibition of Na-K-ATPase, respectively [38, 39, 147]. Other medications can induce hyperkalemia by acting on the angiotensin-aldosterone axis including spironolactone,

Table 2 Causes of hyperkalemia in infants and children

Causes	Examples
Pseudohyperkalemia	Heelstick Finger tip Prolonged tourniquet
Increased potassium load	Diet Oral supplements (KCl, KCitrate, KPhosphate) Intravenous fluids/TPN Blood transfusions Hemorrhages (GI, IVH-in newborns) Hemolysis Rhabdomyolysis Tissue necrosis
Decreased renal excretion	AKI and CKD Hypoaldosteronism/ pseudohypoaldosteronism Urinary obstruction
Drugs	SpironolactoneAmilorideTrimethoprim Nonsteroidal anti-inflammatory drugs Calcineurin inhibitors Heparin Succinylcholine Penicillin G
Redistribution	Acidosis Nonoliguric hyperkalemia of the neonate

indomethacin, and angiotensin converting enzyme inhibitors. Inhibition of ENaC by amiloride and trimethoprim reduces the sodium excretion and potassium excretion [148].

Endogenous potassium load can result from tissue breakdown, gastrointestinal bleeding, and tissue necrosis. Careful attention should also be given to excess oral or intravenous potassium supplementation/nutrition, medications with potassium salts, such as penicillin, or blood transfusions. Acute kidney injury and CKD also result in impairment of urinary potassium excretion. Decreased aldosterone activity, characterized by variable degrees of metabolic acidosis, renal salt wasting, and hyperkalemia, results from a deficiency in mineralocorticoids or resistance to its effects. Aldosterone synthase deficiency is a rare autosomal recessive disease characterized by defective biosynthesis of aldosterone that results in isolated hypoaldosteronism. Patients exhibit salt wasting, recurrent dehydration, hyperkalemia, and failure to thrive. Neonatal screening using 17-hydroxyprogesterone measurement identifies a defect in 21-hydroxylase but fails to detect aldosterone synthase deficiency, a diagnosis which may be missed until the patient presents with a salt-wasting crisis [149, 150]. Pseudohypoaldosteronism is a rare hereditary disorder that results from end-organ resistance to aldosterone, characterized by high plasma aldosterone and renin concentrations. Type I (PHA1) is the result of mutations in the mineralocorticoid receptor (PHA1a or renal PHA) or mutations in the sodium epithelial channel (PHA1b or systemic PHA) [151]. Pseudohyperaldosteronism Type 2 (PHA II; familial hyperkalemic hypertension, FHHt, Gordon Syndrome), a hereditary disorder characterized by hyperkalemia, metabolic acidosis, and hypertension sensitive to thiazide diuretics, results from mutations in the genes encoding WNK1, WNK4, and the ubiquitin-ligase elements Kelch-like 3 and Cullin 3, which are involved in the ubiquitination and degradation of WNK4 (157–161). Hypertension usually develops in late childhood, but the electrolyte disturbances – hyperkalemic acidosis – may be present at birth [152].

Evaluation of Hyperkalemia

The evaluation of hyperkalemia starts by identifying life-threatening signs. Initial ECG changes are prolonged PR interval and peaked T waves, followed by an absence of P wave, widened QRS with S-T depression, and persistent peaked T waves. The QRS continues to widen with higher plasma potassium concentration until ventricular fibrillation develops. Symptoms, such as muscle weakness and hypotension, are rarely observed. One should also assess the blood pressure, as well as volume status and the genitalia since infants with congenital adrenal hyperplasia can present with salt wasting, severe dehydration, hypotension, and virilization.

The laboratory evaluation must include plasma concentrations of sodium, chloride, bicarbonate, creatinine, and a complete blood count. If the GFR is normal and no offending agent can be identified, hypo- or pseudohypoaldosteronism should be ruled out. In these patients, hyperkalemia will be accompanied by hyponatremia and metabolic acidosis. TTKG, with the previously discussed limitations, could assist to discriminate between renal and extrarenal causes. In children with hyperkalemia due to a nonrenal cause, the urinary potassium excretion is very high and therefore the TTKG is high (> 11). In newborns with hypo- and pseudohypoaldosteronism, the TTKG is very low (1.4–4.1) [144]. If an adrenal etiology is suspected, one should measure serum levels of aldosterone, renin, and cortisol.

Treatment of Hyperkalemia

Treatment varies depending on the etiology of hyperkalemia. The intake of potassium should be reduced if indicated. In those with impaired potassium secretion, the cause should be identified. If clinical evidence of volume depletion is present, hyperkalemia may simply reflect inadequate distal sodium delivery and treatment should be aimed at volume expansion.

Therapy targets for hyperkalemia are to prevent arrhythmias and to decrease the plasma concentration of potassium by stimulating a shift into the cell or increasing excretion. If the ECG shows changes consistent with hyperkalemia, calcium gluconate 10% should be administered at a dose of 0.5–1 ml/kg over 5–15 minutes (Fig. 3). The effect stabilizing the cardiac membrane is evident in 1–3 minutes and lasts for 30–60 minutes. The dose may be repeated after 5 minutes if ECG changes persist [153].

Insulin/glucose administration and β2-adrenoreceptor agonists enhance transcellular potassium shifts into the cell. The administration of glucose alone (to induce endogenous insulin release) or glucose plus insulin is efficacious, although patients must be monitored for disturbances in blood glucose, especially in neonates [154–156]. Insulin can be administered at a dose of 0.1–0.6 units/kg/h with glucose infusion of 0.5–1 g/kg/h [157]. The onset of action is approximately15 minutes and lasts few hours. Administration of albuterol/salbutamol via nebulizer has been used to treat acute hyperkalemia in neonates, children, and adults [158–160]. A single dose of nebulized albuterol can lower serum potassium by as much as 0.5 mEq/L [161, 162]. β agonists have a rapid onset of action. It can be administered by a nebulizer at a dose of 400 micrograms (newborns), 2.5 mg (in small children), and up to 5–20 mg in older children and adults [159]. This decreases the plasma concentration of potassium by 0.5–1 mEq/L. Intravenous albuterol at a dose of 4–5 μg/kg, given as an intravenous slow bolus over 5 min, decreases plasma potassium concentration by 0.9–1.5 mEql/L [162].

In the presence of metabolic acidosis, sodium bicarbonate infusion can also promote potassium shifting into the cell. Because it is hyperosmolar and the potential association with intraventricular hemorrhages in premature infants, it should be used very judiciously during the neonatal period [163, 164]. In this case, we recommend a dose of 1 mEq/kg diluted 1:4 in sterile water, administered over 30–60 minutes. The efficacy is questionable in the absence of acidosis. To remove body potassium stores, if the patient is making urine, one could use loop or thiazide diuretics. For severe, unremitting hyperkalemia, dialysis is required. For the removal of potassium from the

Fig. 3 Treatment of hyperkalemia in infants and children. Besides dialysis, sodium polystyrene sulfonate is the only treatment that decreases total body potassium. It can be used at any point if the patient has a normal gastrointestinal (GI) tract. It should be avoided in premature infants. The order of insulin/glucose and albuterol can be changed, according to availability and clinical situation. If the patient is urinating, furosemide can be added at any point to enhance renal potassium excretion

body, resins such as sodium polystyrene 1 g/Kg orally or as enemas can be used. Its efficacy is questionable in neonates [165]. Moreover, because it carries a risk of intestinal perforation and obstruction, it is contraindicated in infants with necrotizing enterocolitis or very premature infants [166]. Newer and more efficacious resins – patiromer and sodium zirconium cyclosilicate – are available for adults, but use in children is currently under investigation [167].

Hypokalemia

Hypokalemia is defined as a plasma potassium concentration lower than 3.5 mEq/L. Since potassium is primarily an intracellular cation, the plasma concentration is not an accurate estimate of total body potassium. Under normal conditions, changes in intracellular potassium concentration parallel serum potassium. Factors that regulate internal potassium distribution may affect this relationship [168]. Cardiac arrhythmias, muscle weakness, and even paralysis are major morbidities associated with severe hypokalemia that requires emergency treatment.

Altered Internal Balance

Hypokalemia due to an altered internal balance should be suspected if there are suggestive factors, such as metabolic alkalosis or evidence of increased insulin activity (Table 1). Treatment in these cases should focus on correcting the underlying abnormality.

Altered External Balance

Hypokalemia due to an altered external balance can be either from excessive potassium loss from the intestine or kidney, insufficient intake, or a combination of these factors. As with hyperkalemia, assessment of the urinary potassium excretion with TTKG may provide useful information to identify the etiology. A low TTKG suggests renal potassium conservation and thus points toward intestinal losses and/or insufficient intake. Conversely, a high TTKG points to renal potassium wasting. In the context of volume depletion, this finding would likely reflect aldosterone-mediated attempts to maintain extracellular volume at the expense of potassium homoeostasis, and volume repletion is the appropriate treatment. Hypokalemia with high TTKG in the presence of hypervolemia and hypertension suggests primary hyperaldosteronism or pseudohyperaldosteronism as seen in some inherited disorders, such as Liddle syndrome or apparent mineralocorticoid excess (Table 3). Pseudohyperaldosteronism can also be acquired, as occurs with licorice abuse [169]. Treatment should focus on the underlying defect. In the short term, or if the underlying problem cannot be targeted, distal potassium secretion can be reduced either by administration of inhibitors of ENaC (amiloride) and/or mineralocorticoid receptor (spironolactone or eplerenone).

Table 3 Causes of hypokalemia in infants and children

Drugs	Amphotericin B Aminoglycosides Thiazides Loop diuretics Corticosteroids
Redistribution (internal shifts)	Alkalosis Insulin Theophylline/caffeine Thyrotoxicosis β agonists, epinephrine

Causes of Hypokalemia

The most common causes of hypokalemia in children are shown in Table 3. Gastrointestinal disturbances such as vomiting, diarrhea, or unreplaced electrolyte losses from nasogastric or intestinal drainage may lead to hypokalemia. Infants with necrotizing enterocolitis or congenital intestinal anomalies requiring surgery of the intestinal tract are at particular risk. Renal potassium losses often result from the use of medications including diuretics, such as furosemide and thiazides or the antifungal amphotericin B (forms pores in cell membrane that allows K^+ to leak out of the cell). The use of the aldosterone inhibitor spironolactone as a potassium-sparing agent may prevent hypokalemia in patients receiving diuretics. Amphotericin B lipid complex is associated with a lower incidence of hypokalemia [170]. Hereditary disorders associated with alkalosis (Bartter and Gitelman syndromes) or acidosis (renal tubular acidosis) cause hypokalemia during the neonatal period. Bartter syndrome, characterized by large sodium losses, is associated with hypokalemic alkalosis and polyhydramnios. Gitelman syndrome usually presents later in life, although hypokalemia has been reported in the newborn period [171]. Renal tubular acidosis, type 1 and 2, often features hypokalemia along with metabolic acidosis. In the Fanconi syndrome, hypokalemia is associated with acidosis, hypophosphatemia, and hypouricemia; the urine is usually dilute with glycosuria, aminoaciduria, and tubular proteinuria. The presence of hypertension in a child with mild hypokalemic alkalosis should prompt the diagnosis of glucocorticoid-remediable aldosteronism, especially if there is familial history of premature cerebrovascular events [172, 173].

Evaluation of Hypokalemia

Severe hypokalemia can cause cardiac arrhythmias, paralytic ileus, muscle weakness, and lethargy. Changes in the ECG include flattened T waves, prolongation of the QT interval, and the appearance of U waves. The primary cause of hypokalemia should be identified and treated accordingly. To this end, a random assessment of the urinary potassium in patients with disturbances of potassium balance is inadequate to assess if the etiology resides in the kidney. Alternatively, given the limitations previously discussed, TTKG may be a helpful tool.

In patients with hypokalemia, the serum concentration of magnesium should be measured as hypokalemia might worsen and become refractory to treatment in the presence of hypomagnesemia [73]. If hypokalemia is associated with polyuria, which is common, intravascular volume should be promptly restored. The rate and route for replacement of potassium depends on the presence of symptoms or changes in ECG.

Treatment of Hypokalemia

The safest treatment of mild asymptomatic hypokalemia is via the oral/enteral route using potassium salts in a dose of 1–2 mEq/kg/day (Fig. 4). In the presence of alkalosis, potassium should be given as KCl to replenish chloride [174]. Moderate to severe (<2.5 mEq/L) symptomatic hypokalemia, or hypokalemia in a patient with gastrointestinal complications who cannot tolerate oral salts, should be treated using intravenous preparations of potassium. The addition of KCl to intravenous fluid (not to exceed 40 mEq/L) can be sufficient in cases of moderate hypokalemia. Higher concentrations (60–80 mEq/L) are required if the patient fails to respond but should be given through a central vein under continuous ECG monitoring. Rapid administration of KCl can lead to life-threatening arrhythmias. In cases of severe (<2 mEq/L) or symptomatic hypokalemia, KCl diluted in normal saline can be carefully given intravenously in doses up to 0.5–1 mEq/kg over 1–2 hours [175]. Continuous ECG monitoring is required. Potassium salts should not be diluted in dextrose-containing solutions as it provokes insulin secretion and cellular potassium uptake, lowering plasma potassium concentration even further [176].

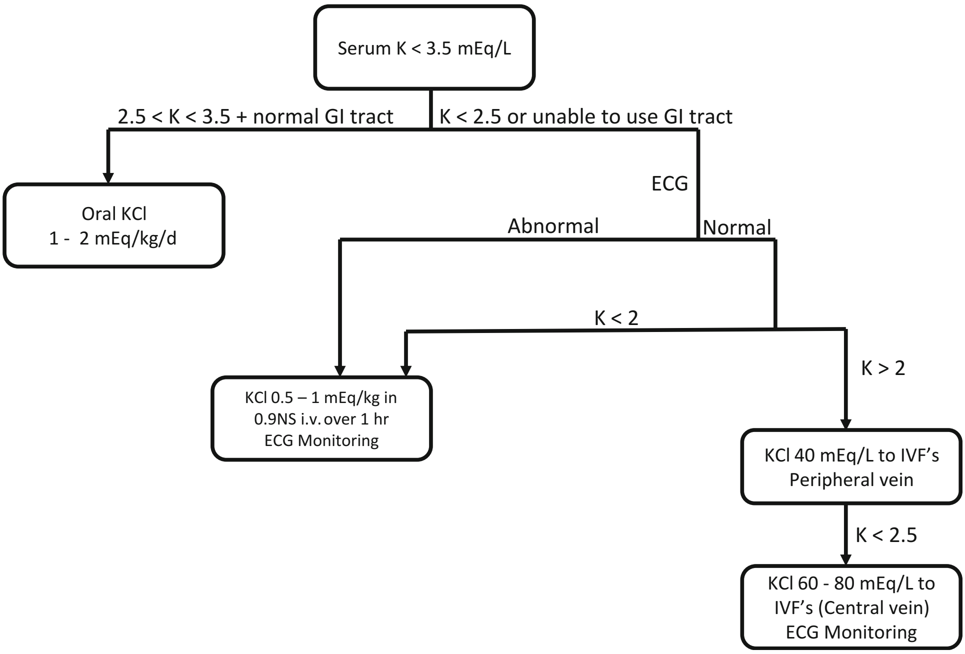

Fig. 4 Treatment of hypokalemia in infants and children. Provided that the patient has a normal GI tract, oral potassium salts should be the initial step in the treatment of mild hypokalemia (K > 2.5 mEq/L). Treatment of severe hypokalemia (K < 2 mEq/L) should be done under continuous ECG monitoring, preferably in a critical care unit. When administering potassium intravenously, always dilute in 0.9NS and not in dextrose as dextrose stimulates insulin secretion and translocation of potassium into the cell, worsening hypokalemia

Dosing and Pharmacokinetic Properties of Commonly Used Diuretics in Pediatrics (Table 2) 1164

References 1164

Abstract

Diuretics are among the most commonly prescribed medications for patients with kidney disease. Most diuretics exert their action by preventing sodium re-absorption from the lumen of the nephron. Since cells must maintain electrochemical neutrality, the direct drug effect on sodium and other electrolytes must be counterbalanced, and must be accounted for as potential side effects. The current chapter will review the specific actions of available diuretics and their applications in clinical settings.

Keywords

Diuretics · Dosing · Pharmacokinetics

Medicinal substances increasing the flow of urine have been recognized in medical writings for over 2000 years. In this chapter we review the physiology of commonly used diuretics on salt and water transport in specific nephron segments and then discuss practical applications of diuretics in clinical pediatric settings. In addition to the importance of diuretics in treating various states of fluid overload, we review additional indications for diuretics in special conditions ranging from kidney stones, to glaucoma, to anxiety.

Introduction

The English word, diuretic, derives from the ancient Greek word, *diouretikos* – referring to any substance that promotes urinary flow. Long lists of plants containing natural diuretics were recognized by Discorides (De Materia Medica) and Pliny the Elder (Naturalis Historia) in the first century [1]. Plants with diuretic properties have been alluded to in Traditional Chinese and Indian medicine writings for over 2000 years [2]. Interestingly, the common dandelion was termed, in Old French, a "Pissenlit" – making reference to bedwetters. However, most naturally occurring diuretics are relatively mild and are of marginal benefit in treating severe edematous states in humans. Clare et al estimate that the diuresis caused by ingestion of an extract of dandelion greens equivalent to an oral dose of 1 g/kg in humans has a diuretic effect equal to a 1 mg/kg dose of furosemide [3] – a potency of about 1:1000.

During the early part of the twentieth century, Western physicians treated edema with mercurials (which proved to be toxic) and various osmotic diuretics such as mannitol and sucrose. However, it was not until 1937 that Southworth made the seminal observation that would lead to the development of the first modern diuretics. He noted a significant diuresis in patients receiving the antibiotic, sulfanilamide. By 1949, Schwartz had used this drug to treat congestive heart failure [4]. Over the ensuing years, Beyer began testing sulfonilamide derivatives for their diuretic properties in animals and finally developed chlorthiazide, the first of the thiazide class of diuretics [5].

Diuretic Sites Along the Nephron

The diuretics commonly used in children can be grouped into five classes, based on the sites of action along the nephron (Fig. 1) (Table 1). Most diuretics circulate in blood bound to albumin and are secreted by proximal tubule transporters into the tubular fluid, where they can inhibit their apical targets. Spironolactone and tolvaptan access their receptor targets from the basolateral surface of tubular cells. Only mannitol is freely filtered through the glomerulus.

Proximal Tubule

The convoluted and straight portions of the renal proximal tubule are richly supplied with mitochondria and are designed for bulk reabsorption of nearly 60% of the filtered load of salt and water

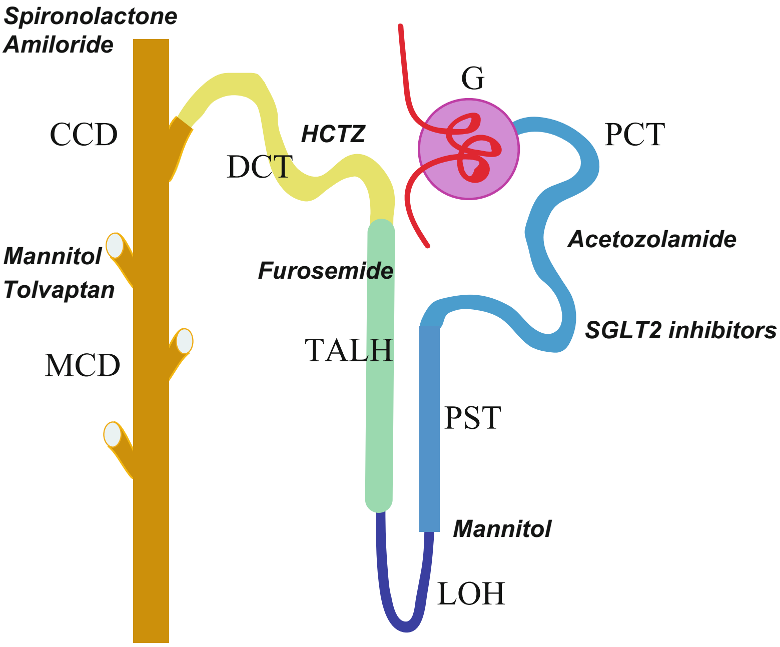

Fig. 1 Diuretic sites of action along the nephron Acetazolamide and gliflozins are transported from blood into the proximal convoluted tubule (PCT segments S1 and S2) lumen, where they inhibit bicarbonate and glucose transport, respectively. Mannitol is freely filtered by the glomerulus and causes an osmotic diuresis by opposing water flux through aquaporin-containing cells in the proximal tubule (AQP1), thin descending limb of the Loop of Henle (AQP1), and collecting ducts (AQP2). Also secreted into the proximal tubule, loop diuretics (e.g., furosemide) inhibit the apical $NaKCl_2$ transporter in the thick ascending limb of the loop of Henle (TAL) while thiazide diuretics (e.g., hydrochlorothiazide) inhibits the apical NaCl symporter in the early portion of the distal convoluted tubule. Cells of the late distal convoluted tubule, connecting tubule, cortical and medullary collecting ducts express the apical, electrogenic sodium channel (ENaC) which is inhibited directly by amiloride (secreted into tubular fluid) and indirectly by spironolactone (in blood). Tolvaptan (in blood) blocks the basolateral vasopressin receptor (V2R) in cortical and medullary collecting ducts, causing a water diuresis

and 95% of organic solutes. Thus, any drugs or pathologic processes that interfere with proximal tubular reabsorption have the potential to cause massive diuresis – overwhelming compensatory distal reabsorption mechanisms. **Acetazolamide,** the first such proximal diuretic, was discovered in 1941. It acts at the apical surface of cells in the proximal tubule as a noncompetitive inhibitor of carbonic anhydrase, thereby decreasing H+ availability for the Na+/H+ exchanger at the luminal membrane (Fig. 2). This limits proximal tubule sodium reabsorption and impairs H+ secretion into the lumen, trapping bicarbonate there. Early studies by Leaf et al. demonstrated its diuretic properties in patients with congestive heart failure, but disappointingly, they found that continued use of acetazolamide inevitably led to acidosis and relative resistance to its diuretic effects after a few days [6]. Although these properties limit the use of acetazolamide as a first line diuretic, it has found several unexpected applications in acute glaucoma (reducing formation of aqueous humor in the ciliary body), high altitude pulmonary edema (mechanism unclear), raised intracranial pressure (reduced production of cerebrospinal fluid), and correction of severe alkalosis [7].

In recent years, a new class of drugs (**gliflozins**) has been developed that inhibit the apical sodium-glucose reabsorption transporter (SGLT2) in the S1 and S2 segments of the renal proximal tubule. Empaglifozin, canagliflozin, and dapagliflozin have been studied extensively for the treatment of Type 2 diabetes mellitus in adults. Despite compensatory mechanisms along the renal tubule, all members of the SGLT2 inhibitor family are

Table 1 Diuretic action in the nephron segments

Diuretic	Target	Nephron Segment	Use	Dose/kg	MAX	Comment	References
Acetazolamide	CAII	PT	Papilledema	8–30 mg/kg q8h		Accumulates in ESRD	[82]
			Glaucoma	3–6 mg/kg q8h	1000 mg/day	3–10 mg/kg <12 years	[83]
			Alkalosis	5 mg/kg q24h X 3 days			
			High altitude	2.5 mg/kg q12h		Day before and of ascent	[84]
			Seizure disorder	1–4 mg/kg q6 h	16 mg/kg/day		[85]
Canagliflozin	SGLT2	PT	Diabetic nephropathy	100–300 q24h			[86]
Empagliflozin	SGLT2			10–25 mg q24h			[87]
Dapagliflozin	SGLT2			5–10 mg q24h			[88]
Mannitol	Aquaporin channels	PT, TDL CCT,MCT	Cerebral edema	0.5–1.0 g/kg (20–30 min)	Serum osm < 320		[89]
			Dialysis disequilibrium	0.5–1.0 g/kg	50% during hr. 1, 25% during hrs 2–3		[90]
Furosemide	NA-K-2Cl (NKCC2)	TAL	Starting intermittent oral	1.0–2.0 mg/kg	100 mg/day	Not dialyzable	[91]
			Starting intermittent iv	0.5–2.0 mg/kg			
			Titrate to achieve diuresis	1–2 mg/kg q6-8hrs	6 mg/kg/day	Can add HCTZ or amiloride	[92]
			Continuous infusion				
			Loading dose	0.1 mg/kg

			Neonate (po) <31 weeks GA	0.5–2.0 mg/kg q24h			[94]
			Neonate (po) >31 weeks GA	0.5–2.0 mg/kg q12h			
			Neonate (iv) <31 weeks GA	1 mg/kg q24h			
			Neonate (iv) >31 weeks GA	1 mg/kg q12-24 h			
Bumetanide	Na-K-2Cl (NKCC2)	TAL	Edema	0.01–0.1 mg/kg/ dose		2.5% of furosemide dose	[95]
			Continuous infusion	6ug/kg/hr			[46]
Hydrochlorothiazide	NaCl symporter (NCC)	DCT1	Edema, furosemide resistance	0.25–1.0 mg/kg q12h		With furosemide or amiloride	[97]
			Calcium nephrolithiasis	0.25–1.0 mg/kg q12h			
Chlorthalidone	NaCl symporter (NCC)	DCT1	Edema or hypertension	0.1–0.3 mg/kg q24h	2 mg/kg/day	Monotherapy or with furosemide	[97, 98]
Metolazone	NaCl symporter (NCC)	DCT1	Edema	0.1–0.2 mg/kg q12h		With furosemide	[99]
Amiloride	Na + channel (ENaC)	DCT2, CCD, MCD	Hypertension	0.4–0.625 mg/ kg/day		With HCTZ or furosemide	[17]
			Edema	0.625 mg/kg/day		Monitor K+	[17]
			NDI	0.1 mg/kg q8h	12 mg/m^2/day	With HCTZ 2 mg/kg/d	[100]
Spironolactone	Na + channel (ENaC)	DCT2, CCD, MCD	Edema	1–3 mg/kg/day		With furosemide (ratio 2:5)	[92]
			Ascites	1–3 mg/kg/day	6 mg/kg/day	With furosemide or alone	[66]
Tolvaptan	ADH receptor II (V2R)	CCD, MCD	Hyponatremia	0.05–0.3 mg/kg/ day		Start at low dose, titrate	[101]

CAII – cytoplasmic carbonic anhydrase, PT – proximal tubule, SGLT-2 – sodium glucose transporter, TDL – thin descending limb, CCT – cortical collecting duct, medullary collecting duct, TAL – thick ascending limb, HCTZ – hydrochlorothiazide, NKCC2 – Na/K/Cl2 , DCT – distal collecting duct, ENaC – electrogenic apical sodium channel, ADH – anti-diuretic hormone, V2R – vasopressin 2 receptor

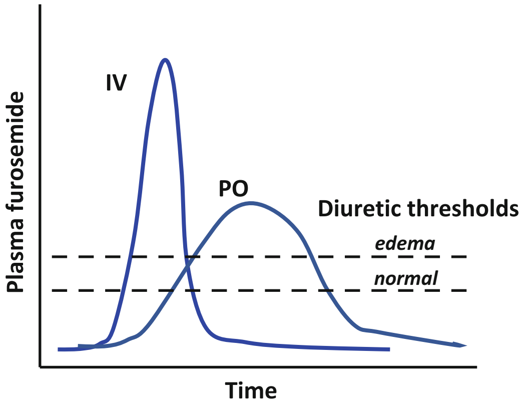

Fig. 2 Tubular fluid threshold for loop diuretics Intravenous furosemide circulates in blood >95% bound to albumin, largely precluding filtration through the renal glomerulus (Ellison CJASN 2019). However, it is rapidly transported across the basolateral membrane of proximal tubular cells into tubular fluid at concentrations that inhibit the TAL apical $NaKCl_2$ transporter; elimination half-life is also rapid, and duration of diuresis is about 2 hours. When administered orally, furosemide is absorbed slowly, reducing the serum peak concentration but extending the period of time during which tubular fluid concentrations exceed the threshold for transporter inhibition; diuresis lasts for about 6 hours. However, in edematous states, the threshold for $NaKCL_2$ inhibition is elevated and significantly higher doses are required to achieve the same diuresis. Similarly, proximal tubular cell injury may limit the rate of delivery into tubular fluid, increasing the minimal effective dose to 2–4 mg/kg

moderately potent diuretics. In rats with type 2 diabetes mellitus, Masuda et al showed that oral gliflozins cause a sustained increase in urine volume (80%), natriuresis (40%), and free water clearance (15%) [8]. Although gliflozins do not block the SGLT1 sodium-glucose transporter in the proximal tubule S3 segment, this secondary high-affinity low-capacity transporter is overwhelmed when the upstream mechanism is lost. There is now great interest in the cardiorenal protective effects of these drugs, in addition to their ability to improve diabetic control.

Thick Ascending Limb of the Loop of Henle

Furosemide is an organic anion that blocks the apical Na/K/Cl2 transporter (NKCC2, encoded by SLC12A1) (Fig. 3) and inhibits by interacting with chloride-binding site – without being transported into cell. Furosemide must gain access to the tubular fluid compartment in order to be effective. Bioavailability of an oral dose is about 50–60% [9]. Since furosemide circulates in blood bound to albumin, its clearance through the glomerulus is very low and enters the tubular fluid primarily by proximal tubule secretion pathway – using OAT1 and OAT2 transporters for uptake at the basolateral surface [9]. The drug is concentrated in the proximal tubular cell and diffuses passively across the apical surface into the proximal tubular lumen. Other loop diuretics such as bumetanide, torsemide, and neseritide have slightly better oral bioavailability (80%) and more rapid uptake from the intestine, but shorter half-life.

Furosemide and the other loop diuretics all target the same $NaKCl_2$ transporter, NKCC2, (encoded by the SLC12A1 gene) at the apical surface of cells in the thick ascending limb of the loop of Henle. At very high dose, these drugs inhibit up to 25% of the filtered load of sodium [10]. While TAL cells transfer sodium and chloride ions across the basolateral membrane into the interstitium, potassium is pumped back across the apical membrane via the ATP-dependent ROMK channel. This establishes a positive electrical potential in the lumen that enhances reabsorption of calcium and magnesium through paracellular pathways. By ablating lumen positivity, furosemide compromises divalent cation reabsorption, causing hypercalciuria, and hypermagnesuria. Since the TAL is impermeable to water, normal NKCC2 function dilutes tubular fluid and establishes a hyperosmotic medullary interstitium. Conversely, furosemide blunts the osmotic gradient that allows vasopressin-driven water reabsorption along the collecting duct; this can be useful in allowing free water excretion in treating some hyponatremic states. With sustained NaKCC2 blockade, the resultant volume contraction powerfully stimulates aldosterone-driven reabsorption of sodium in the collecting tubule in exchange for hydrogen ion and potassium. Hypokalemia and alkalosis may present undesirable effects which limit furosemide in patients with normal tubular function or may be useful

Overshoot (Excessive edema)
Euvolemia

Fig. 3 Fluid overload during treatment of shock
During resuscitation of critically ill children, intravenous fluid boluses are administered over minutes to hours in an effort to repair any dehydration and capillary leak that produce an "underfilled" state. As blood pressure and tissue perfusion are stabilized, attention turns to infusion of blood products, drugs, and intravenous alimentation. However, in the presence of acute kidney injury, oligoanuria may lead to fluid overload, organ edema, and organ dysfunction associated with poor outcome. Early diuretic use is essential to avoid excessive fluid overload beyond 10% of basal body weight. Sustained diuretic use accelerates return to euvolemia, and reduced hospital stay

consequences of loop diuretics in chronic or acute kidney failure.

Furosemide and the other loop diuretics can cause hearing loss in humans at very high doses >1 gram or infusion rates >250 mg/hr. [11]. The risk of hearing loss may be greater in patients with renal insufficiency (GFR <20 ml/min/1.73m^2) or concurrent ototoxic agents such as gentamicin [12]. Furosemide toxicity appears to involve inhibition of a $NaKCl_2$ homolog (encoded by the SLC12A2 gene) in the inner ear stria vascularis. Mice with targeted knockout of the SLC12A2 have structural damage in the inner ear and are deaf [13]. Ototoxicity seems to be linked to speed of the furosemide infusion and peak levels rather than total dose [14].

Early Distal Convoluted Tubule

Hydrochlorothazide and related thiazide-like diuretics (chlorthalidone and metolazone) are taken up into proximal tubular cells by the basolateral organic base secretory mechanism and secreted into the tubular lumen (Fig. 4). They target the downstream apical sodium chloride symporter (NCC, encoded by the SLC12A3 gene) in the early portion of the distal convoluted tubule (DCT1) [9]. NCC is an electroneutral transporter that can reabsorb 3–5% of the filtered sodium load, but, unlike the $NaKCl_2$ transporter in the TAL, it does not generate a negative luminal potential driving divalent cation reabsorption via the paracellular pathway. Instead, calcium and magnesium enter DCT1 cells via selective channels (TRPV5 and TRPV6, respectively) and are pumped across the basolateral membrane by diuretic-independent mechanisms [15]. On the other hand, the natriuretic effect of thiazide diuretics establishes a state of volume contraction which heightens $NaKCl_2$ transporter activity and indirectly enhances divalent cation reabsorption in the late TAL and DCT1 segments. In the DCT2 and collecting tubule, volume contraction drives

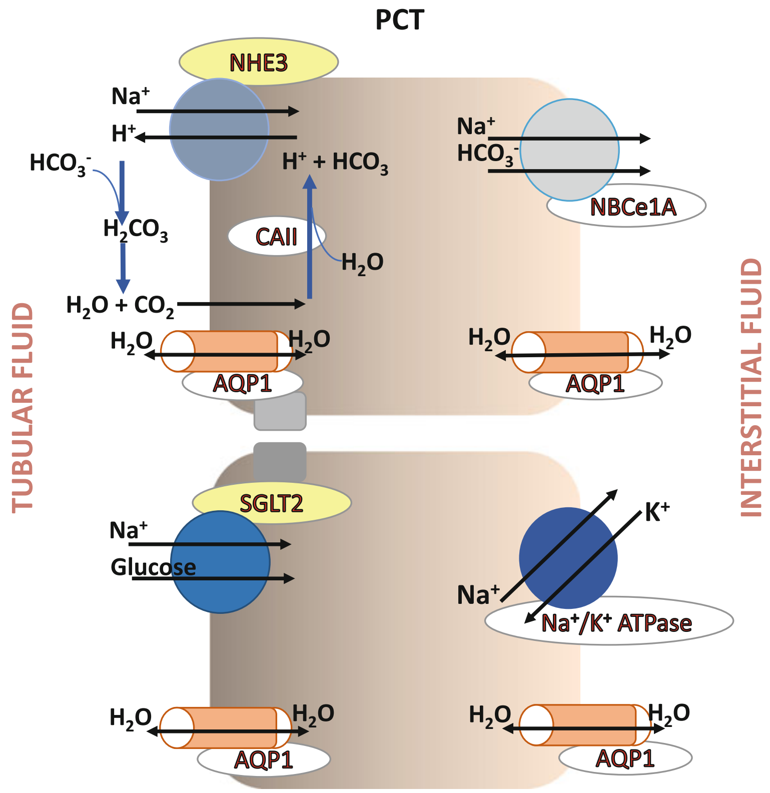

Fig. 4 Diuretics acting on the renal proximal tubule **Acetazolamide** is taken up by the organic anion transporters (OATs) into cells of the proximal tubules, where it inhibits the cytoplasmic (CAII) and brush border (CAIV) forms of carbonic anhydrase. By blocking the interconversion of carbonic acid and CO_2, the reabsorption of sodium bicarbonate from tubular fluid is inhibited, causing a moderate diuresis, alkalinization of the tubular fluid and proximal tubular acidosis. **Gliflozins** (e.g., empagliflozin, canagliflozin, and dapagliflozin) are taken up by basolateral organic anion transporters in the S1 and S2 segments of the proximal convoluted tubule and secreted into tubular fluid where they inhibit the apical Na/glucose transporter (SGLT2). The resultant glucosuria overwhelms the downstream low-capacity SGLT1 transporter, causing moderate water diuresis and mild natriuresis

K+ and H+ secretion as described below. Thus, thiazide diuretic inhibition of NCC in the DCT1 segment produces moderate natriuresis, hypocalciuria/hypomagnesuria, and hypokalemic alkalosis.

Late Distal Nephron (DCT2, CNT, CCD, MCD)

Amiloride is a pyrazine derivative that blocks the electrogenic apical sodium channel (ENaC) in principal cells throughout the late DCT2, connecting tubule (CNT), cortical (CCT), and medullary collecting tubules (MCT) [16]. ENaC is made up of four subunits, encoded by SCNN1A, SCNN1B, SCNN1G, and SCNN1D, respectively). While amiloride causes only a modest natriuresis (up to 1–2% of the filtered sodium load), it also blocks the ENaC-generated negative luminal charge that normally facilitates potassium (via the apical ROMK channel) and hydrogen ion secretion (via the hydrogen ion V-ATPase transporter) in nearby alpha-intercalated cells (Fig. 5). Thus, amiloride is often used in combination with thiazides or loop diuretics, to enhance diuresis while offsetting hypokalemia and alkalosis [17]. However, amiloride can only block a portion of tubular potassium loss; high urinary flow is now recognized to activate maxi-K channels in the alpha-intercalated cell apical membrane. This flow-dependent potassium secretion is

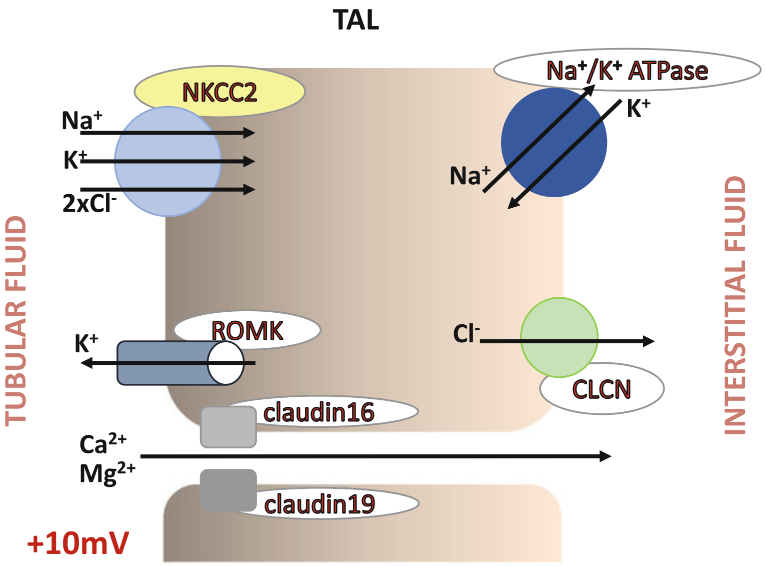

Fig. 5 Loop diuretics
Furosemide and other loop diuretics (e.g., bumetanide and torsemide) are secreted into proximal tubular fluid and target the apical $NaKCL_2$ transporter (NKCC2, encoded by SLC12A1) in the thick ascending limb of the loop of Henle (TAL). Normally, this electrically neutral transporter reabsorbs about 25–30% of filtered sodium. Sodium and chloride ions exit via the basolateral membrane while potassium is recycled to the lumen, generating a + 10 mV potential that drives calcium and magnesium reabsorption through the paracellular pathway. Furosemide blockade of NKCC2 rapidly causes natriuresis, hypercalciuria, hypermagnesuria; compensatory sodium reabsorption via the distal ENaC leads to hypokalemic alkalosis

independent of ENac and is unaffected by amiloride. By inhibiting ENaC function, amiloride is an effective antihypertensive agent in Liddle syndrome caused by autosomal dominant ENaC mutations that cause unregulated, hyper-reabsorption of sodium [18].

Interestingly, there are now reports that amiloride may be useful in treating anxiety disorders and has been adapted as a nasal spray for this purpose [19]. It is also useful in hereditary and lithium-induced nephrogenic diabetes insipidus in combination with thiazide diuretics. By causing volume contraction, water reabsorption is stimulated in the proximal tubule via aquaporin I channels.

Volume contraction produced by thiazides or loop diuretics predictably induces distal nephron compensatory mechanisms driven by increased blood levels of aldosterone. These effects include upregulation of principal cell ENaC itself, the basolateral Na-K ATPase, and the apical potassium secretory channel (ROMK). Thus, drugs that inhibit the aldosterone receptor, such as spironolactone and eplerenone, compromise ENaC function. Like amiloride, these drugs cause diuresis and block the generation of an electronegative luminal potential which drives potassium excretion and urinary acidification. They are useful as potassium-sparing diuretics in combination with thiazides or loop diuretics in heart failure and ascites. However, they must be used cautiously in patients with chronic kidney dysfunction, since they may cause unwanted hyperkalemia and acidosis. Significant side effects of spironolactone include gynecomastia in boys and vaginal bleeding in girls, but eplerenone lacks these complications.

Aquaporin-Containing Segments: Collecting Duct and Proximal Tubule/ Thin Descending Limb of the Loop of Henle.

Mannitol is an osmotically active polyalcohol sugar which is not orally absorbed and minimally metabolized. When injected intravenously, it is freely filtered through the glomerulus and is not reabsorbed during its passage along the renal tubule. Thus, it causes a water diuresis at nephron segments containing aquaporins, where water is freely permeable (Fig. 6). Its main site of action is in the proximal tubule and thin descending limb of the loop of Henle (AQP1) but also opposes vasopressin action AQP2 in the cortical and medullary collecting tubule (AQP2) [10]. Through a solvent drag effect, there is a mild natriuresis, but the water diuresis dominates and can eventually lead to hypernatremia. In normal individuals, about 80% of the drug is excreted in the urine over 10 hours; typical intravenous dose of 0.5–1.0 mg/kg infused over 2–6 hours usually produces urine flow rates of

Mannitol can be used to treat oliguria in states of fluid overload, but it is more commonly used to treat acute brain edema (1–2mg/kg over 30–60 minutes) through its effects on water movement out of the brain compartment and through indirect effects to contract the brain vascular volume [20]. It is also used to avert dialysis disequilibrium syndrome when pre-dialysis blood urea nitrogen exceeds 35 mM; a dose of 0.5–1.0 mg/kg is infused over the first 3 hours of a 5-hour dialysis session (50% in the first hour and 25% in each of the next 2 hours).

Mannitol diuresis protects against cisplatin-induced nephrotoxicity above the benefit from hyperhydration protocols alone [21]. Evidence in rats shows that cisplatin in the glomerular filtrate enters proximal tubular cells from the apical surface and contributes significantly to nephrotoxicity; mannitol diuresis markedly reduces cisplatin concentration in the tubular fluid [22].

Tolvaptan is a selective competitive inhibitor of the vasopressin receptor 2 and blocks aquaporin2-mediated water reabsorption in principal cells of the cortical and medullary collecting tubules (Fig. 6). By producing a pure water diuresis, it is useful in treating refractory hyponatremia in hospitalized adults with the syndrome of inappropriate antidiuretic hormone, congestive heart failure, or cirrhosis [23]. In hospitalized children, it has been used to treat severe hyponatremia of nephrotic syndrome, using a progressively increasing dose from 0.3–3.0 mg/kg/day to avoid overly-rapid correction of serum sodium or at a fixed dose of 0.35–0.45 mg/kg to prevent or correct mild hyponatremia following cardiac surgery [24, 25].

Clinical Use of Loop Diuretics in States of Acute Volume Overload

Figure 7 compares the basic pharmacokinetic patterns of iv and oral doses of furosemide in normal humans. Diuresis occurs when blood levels of drug generate sufficient intratubular concentrations to

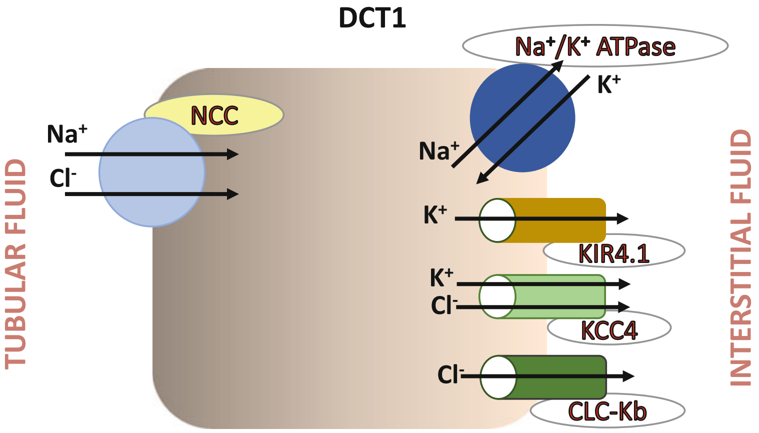

Fig. 6 Thiazide diuretics
Hydrochlorothiazide and other thiazide diuretics (e.g., metolazone, chlorthalidone) inhibit the apical electroneutral NaCl co-transporter (NCC, encoded by *SLC12A3*) in the early part of the distal convoluted tubule (DCT1) and can block up to 3–5% of the filtered load of sodium chloride. Like loop diuretics, the thiazides are secreted into the tubular lumen by proximal tubular to reach their apical DCT1 target

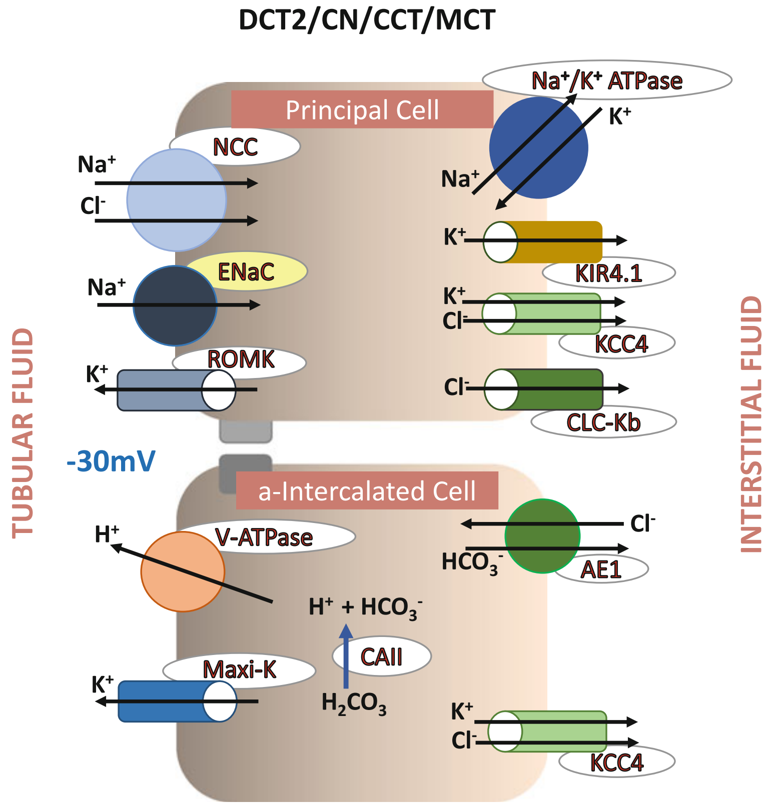

Fig. 7 Amiloride sensitive diuretics
Amiloride is a "potassium sparing" diuretic that inhibits the apical sodium channel (ENaC) expressed by principal cells throughout the late distal convoluted tubule (DCT2), connecting segment (CN), cortical (CCD), and medullary (MCD) collecting ducts. Amiloride secreted into tubular fluid can inhibit about 1–2% of the filtered load of sodium chloride. This electrogenic transport generates a –30 mV luminal potential that drives secretion of potassium via principal cell ROMK channels and both hydrogen (V-ATPase) and potassium (Maxi-K) ions from adjacent alpha-intercalated cells. Spironolactone and other "potassium sparing" diuretics (e.g., eplerenone and finerenone) exert a similar effect by inhibiting the mineralocorticoid receptor which regulates ENaC expression and function

exceed the threshold for significant $NaKCl_2$ transporter inhibition in the downstream thick ascending limb of the Loop of Henle. Note that the threshold to achieve diuresis is increased in many edematous states. Healthy adult volunteers taking a modest oral dose (0.25–0.4 mg/kg) of furosemide notice onset of diuresis within 2–4 hours and increased urine flow for about 6 hours [9]. After an intravenous bolus, onset of diuresis may be noted after 30–60 minutes. In either case, as diuresis subsides, the net natriuresis results in acute contraction of central volume that induces a period of increased sodium reabsorption, positive fluid balance, and kaliuresis, driven by distal nephron compensatory response. Thus, if a sustained state of relative volume contraction is desired, repeated doses of furosemide are needed – typically an oral dose q12 hours with oral potassium supplementation to prevent hypokalemia. Alternatively, a lower dose of loop diuretic may be combined with one of the potassium-sparing diuretics (e.g., spironolactone or amiloride) to minimize the amount of potassium supplement required.

With repeated administration of furosemide, there is often a progressive decrease in the diuretic response after a few days. This "braking" phenomenon reflects several compensatory mechanisms, including hypertrophy of the renal tubule (including the thick ascending limb of the loop of Henle) and increased aldosterone-driven stimulation of sodium reabsorption in the cortical collecting tubule. Sustained volume contraction may also compromise renal blood flow, uptake of furosemide via the proximal tubule OAT secretory system and thus the rate of furosemide delivery into the tubular lumen. The braking phenomenon has been well-described in adults and has been documented in children after about 72 hours of repeated dosing [26]. Kim et al. showed that positive fluid balance rises steadily from the third day of therapy onward, as the calculated natriuresis per mg of furosemide falls [26]. In the acute care setting, this effect is usually dealt with by increasing the furosemide dose, the frequency of furosemide doses or by the addition of distal acting diuretics. In the intensive care unit, a continuous infusion protocol may be considered. This may provide a more predictable diuresis with a modest reduction in total furosemide dose, but does not seem to produce a more potent diuresis than can be achieved with intermittent dosing [27].

Furosemide resistance can be seen in a variety of pathologic states. With fluid overload, bowel wall edema compromises absorption and the oral dose is estimated to be about twice the intravenous dose to achieve the same level of diuresis [9]. In chronic kidney disease, sodium reabsorption is suppressed in the residual nephrons as a compensatory response to falling GFR. Hypoalbuminemia causes an “underfilled” state which increases distal salt and water reabsorption that counters the upstream effect of furosemide on the TAL. There are no known mutations of the OAT that block furosemide secretion into the tubular lumen, but this becomes a critical issue in acute tubular necrosis or chronic progressive renal disease. In acute tubular necrosis, high doses of furosemide (4 mg/kg/dose) are needed to optimize the rate of delivery to the lumen and lift luminal furosemide levels above the threshold for $NaKCl_2$ inhibition. Since ATN also decreases renal clearance of furosemide, dosing frequency can be lengthened to every 24 hours in end-stage renal disease. Secretion of furosemide may be mildly diminished by NSAIDS which reduce renal blood flow or by drugs that share the OAT secretory mechanism, causing furosemide resistance by competing for delivery into the tubular lumen.

All loop diuretics target the apical $NaKCl_2$ transporter, but some may have pharmacokinetic advantages in certain clinical settings. Bumetanide is 40 times (mg/mg) more potent than furosemide and is approved by the FDA for children. Since bumetanide is cleared significantly by the liver, this ratio drops to about 20:1 in chronic renal failure; drug accumulation to ototoxic levels may be less likely with bumetanide than with furosemide but this has not been directly proven at equivalent diuretic doses. Small studies suggest intermittent bumetanide dosing from 0.015 to 0.1 mg/kg/dose every 6 to 24 hours for infants and children. There is no reported additional clinical benefit in infants with doses above 0.05 mg/kg and no increased diuresis compared to a 40X dose of furosemide. In adolescents, typical doses range from 0.5 to 1 mg/dose every 6 to 24 hours (max dose 10 mg/day).

Torsemide is two times more potent than furosemide and has a longer half-life. In adults with congestive heart failure, torsemide is associated with better functional improvement and decreased cardiac mortality [28]. However, there is no FDA-labeled indication for children and no strong rationale for torsemide continuous infusion. Ethacrynic acid does not contain a sulfonamide group, so is suitable for patients with sulfa allergies. It is 30% less potent than furosemide and has greater incidence of ototoxicity. The FDA has approved ethacrynic acid for treating edema in children older than 1 year old at a dose of 1 mg/kg/dose every 8 to 12 h (max 50 mg/dose) but its use has decreased because of its greater irreversible ototoxicity compared to furosemide [29].

Diuretics in Specific Clinical Settings

Acute Post-Infectious Glomerulonephritis (APSGN)

In APSGN, glomerular filtration may fall dramatically but tubular function is relatively well preserved. Rapid onset of fluid overload is accompanied by hypertension and hyperkalemia which respond readily to diuretics. At presentation, early introduction of furosemide may avert the need for hospitalization by reducing the volume-dependent component of hypertension and whole-body potassium accumulation. Unlike acute tubular necrosis where proximal tubule secretion of diuretics is sharply impaired, an oral dose of furosemide (2 mg/kg) is efficiently transferred to the tubular lumen and causes timely diuresis and kaliuresis over 6–8 hours. Intermittent oral dosing over the next days is often sufficient for outpatient management.

Nephrotic Syndrome

In steroid-sensitive nephrotic syndrome, edema may be massive but is likely to resolve after 2 weeks of prednisone therapy. Furthermore, severe hypoalbuminemia causes marked contraction of central volume and overly aggressive diuresis may cause hypotension. Thus, edema is usually managed with low salt intake alone without diuretics. However, some children with massive edema may experience skin breakdown, respiratory difficulty, gastrointestinal symptoms, or mechanical discomfort. They may also develop significant hyponatremia. In these settings, cautious diuresis typically involves oral furosemide (1–2 mg/kg/day) allows partial mobilization of edema and improvement in hyponatremia. When response to furosemide is suboptimal, iv furosemide can be administered toward the end of a 2–4 hour infusion of 25% albumin (0.5 g/kg) [30]. However, albumin infusion moves interstitial fluid into the vascular compartment and enhances furosemide-induced diuresis but, if given too rapidly, may rarely precipitate pulmonary edema [30]. To reverse this shift of fluid into the alveolar space, vasodilators (to increase intravascular capacitance) such as nifedipine or nitroglycerin patch are said to be rapidly effective but have not been carefully evaluated.

Meena et al have reported an alternative protocol in which oral tolvaptan (0.5–1.0 mg/kg/day) administered in combination with intravenous furosemide (3–4 mg/kg/day) for 2 days [31]. This approach avoids the rare pulmonary complications of albumin infusion and uses a diuretic which is unaffected by the serum albumin concentration. However, prospective studies in larger numbers of children are needed to refine this protocol and establish safety.

Chronic Congestive Heart Failure

Diuresis is essential in the setting of congestive heart failure. A typical situation is the baby who has undergone cardiac surgery for a congenital defect and is left with reduced ejection fraction despite ionotropic agents and an ACE inhibitor to reduce afterload. Peripheral and pulmonary edema may initially respond to a loop diuretic (e.g., 0.5 mg/kg furosemide twice daily), but may become complicated by emergence of the "braking phenomenon" and rise in serum creatinine.

The first dilemma is whether to increase furosemide dose or increase the frequency of furosemide doses. Since primary myocardial failure may represent an underfilled state, pediatricians may be reluctant to increase diuresis because further volume reduction could reduce renal perfusion and lower GFR. However, it must be remembered that congestive heart failure causes widespread venous congestion; the rise in intraperitoneal venous pressure and the increase in renal edema alter the pressure gradient driving filtration across the glomerular capillary wall and reduces GFR. Diuresis is crucial to reduce edema in this setting and warrants an increase in furosemide dosing [28]. Since the diuretic threshold for loop diuretics is elevated in diuretic states, it is common practice to double the furosemide dose (or number of doses per day) to achieve a significant increase in diuresis [10]. Alternatively, diuresis can be accomplished by adding a distal-acting diuretic (the choice of which is guided by serum potassium). A thiazide is typically added if serum potassium is normal [32], whereas a potassium sparing diuretic (aldactone or amiloride) may be preferable if there is hypokalemia [33]. To avoid compromise of cardiac filling pressures, diuresis should usually be limited to 1–2% of body weight per day.

Although ACE inhibitors are useful for afterload reduction in heart failure, it may be useful to hold (or reduce) these drugs during periods of cardiac decompensation. Since successful diuresis is dependent on GFR, continuation of ACE inhibitors may compromise intraglomerular pressure, causing elevated serum creatinine and further resistance to furosemide.

Treatment of Shock in the PICU

The principles of resuscitation during critical illness are based on improving oxygen delivery relative to oxygen demand. Therapeutic interventions are predicated on improving gas exchange in the lungs, optimizing cardiac output, and normalizing systemic blood pressure. Pulmonary gas exchange may be compromised by fluid overload while cardiac output is dependent on preload, myocardial contractility, and afterload. Thus, manipulation of total body water and its distribution is fundamental to critical care. The goal is to achieve a s*ufficient volume*, vasomotor tone, and cardiac contractile performance that sustain tissue perfusion relative to metabolic needs. While aggressive volume expansion is crucial during the early phase of circulatory failure, this inevitably leads to total body water overload, organ edema, and dysfunction and a requirement for aggressive use of diuretics during the recovery phase.

A recent systematic review (44 studies with 7507 children) addressed the negative impact of acute fluid overload on worsening of respiratory function (pulmonary edema), development of acute kidney injury, longer intensive care stay, and death [34]. The odds of death were increased 6% for every 1% increase in fluid overload, independent of disease severity. Fluid overload may affect all critical organs [35]:

- Cerebral edema: impaired cognition, delirium.
- Myocardial edema: conduction disturbance, impaired contractility, diastolic dysfunction.
- Pulmonary edema: impaired gas exchange, reduced compliance, increased work of breathing.
- Renal interstitial edema: reduced renal blood flow, increased interstitial pressure, reduced glomerular filtration rate, uremia, salt and water retention.
- Hepatic congestion: impaired synthetic function, cholestasis.
- Gut edema: malabsorption, ileus.
- Tissue edema: poor wound healing, wound infection, pressure ulceration.

Vincent and De Backer [36] proposed that treatment of shock could be envisioned in distinct temporal phases.

1. **Rescue (minutes; severe shock):** administration of lifesaving fluid to achieve perfusion pressure and cardiac output compatible with immediate survival (shock correction). Fluid therapy is given as rapid boluses.
2. **Optimization (hours; unstable patients):** organ rescue by maintaining tissue perfusion. This needs careful monitoring of cardiac output, mixed venous oxygen saturation (SvO2), and lactate levels. Fluid challenges may be used to assess reversibility of oliguria.
3. **Stabilization (days; stable patient):** maintenance of stable volume expansion to preserve organ function, while avoiding excessive fluid overload. Aim for zero or negative fluid.
4. **De-escalation (days to weeks; recovery):** organ recovery with the goal of mobilizing accumulated fluid providing treatments to help achieve negative fluid balance.

Goldstein [37] later simplified this scheme, allowing focus on diuretics:

A) Resuscitation Phase, combining immediate and subsequent steps in volume expansion – diuretics are not usually employed.

B) Maintenance Phase, as the underlying cause of shock is dealt and attention turns to nutrition, blood products, and secondary complications (diuretics are important to maintain neutral fluid balance).

C) Recovery Phase (diuretics are important to achieve reduction of fluid overload) (Fig. 3).

Diuretic therapy is often introduced during transition from the resuscitation to maintenance phases. Loop diuretics are the mainstay of this effort, due to their rapid onset action and potency. In stable patients, intermittent doses of furosemide range from 0.5 to 2 mg/kg/dose every 6 to 12 h (maximum 6 mg/kg/dose or 200 mg/dose in adults). Naïve patients might need a smaller initial dose. While loop diuretics are useful in critically ill children with residual renal function, they are ineffective when GFR is fallen to zero or proximal tubule cell death precludes delivery of drug into the tubular lumen. Renal dimercaptosuccinic acid scans may be useful in detecting viable proximal tubular cells, so that recovery from acute tubular necrosis may be possible [38]. In the setting of oligo-anuria following resuscitation from shock, a challenge with a single high-dose (2–4 mg/kg) of furosemide may unmask residual GFR.

While diuretics do not prevent or reverse ischemic kidney injury [39], they are essential for managing fluid overload during the maintenance phase of therapy for shock. Vasudevan has suggested that the net volume expansion needed to compensate for “third-spacing,” blood pressure support and delivery of critical medications is ideally kept below 10% of pre-morbid weight [40]. However, the need for non-resuscitation fluid during the maintenance phase (blood products, intravenous medications, parenteral nutrition, and fluid boluses to maintain blood pressure in unstable patients) frequently leads to excessive fluid overload (Fig. 8) and secondary organ edema. Barhight et al. found in a study of 14,483 critically ill children, that about 75%, 20%, and 5% received non-resuscitation fluids accounting for $<10\%$, 10–20%, and $> 20\%$ fluid overload, respectively, by the third day of admission [41]. Every 1% fluid overload was associated with a 1% increase in mortality, and a 1% decrease in the likelihood of a ventilator-free day [41]. This suggests that a continuous estimate of fluid load as a percent of pre-morbid body weight should be kept (when this can be obtained from parents or estimated from recent medical records) and that aggressive diuretic use should be used in the maintenance phase to avoid fluid overload above 10% of baseline body weight.

In patients who exhibit resistance to loop diuretics, thiazides (acting in the distal convoluted tubule) and/or diuretics acting in the collecting tubules (e.g., amiloride or spironolactone) are frequently added. The latter potassium-sparing agents are preferable in patients with hypokalemia. However, a recent retrospective study of 448 patients showed that spironolactone supplementation did not significantly reduce the need for potassium supplementation in one cardiac pediatric intensive care unit [42].

In patients with hemodynamic instability, loop diuretics may be administered as a continuous infusion. This appears to have less effect on central venous pressure, oxygen saturation, and heart rate compared to intermittent dosing [43]. In 2014, Miller et al published an extensive literature review on the use of continuous-infusion (CI) loop diuretics in critically ill children

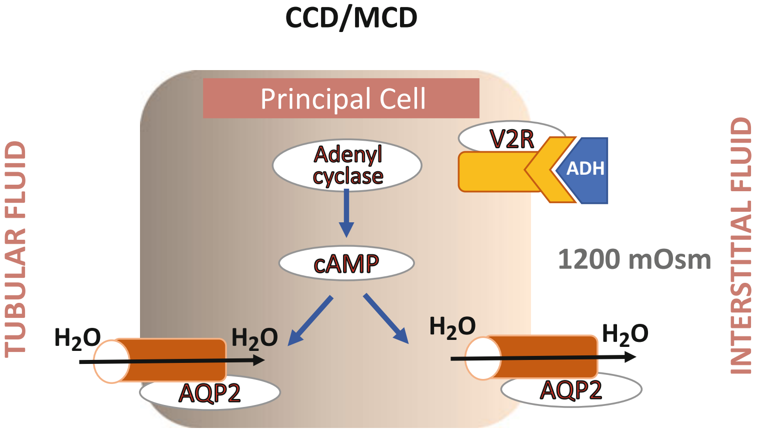

Fig. 8 Osmotic diuretics
Mannitol is a polyalcohol that is freely filtered at the glomerulus and is not reabsorbed by the renal tubule. Through its osmotic properties, mannitol opposes flux of water in aquaporin-containing cells of the medullary collecting ducts and thin Loop of Henle. In the collecting ducts, water reabsorption through the aquaporins can be blocked directly by **Tolvaptan**

[44]. Compared with intermittent dosing, there were no significant differences in urine output, but continuous infusions appear to produce a more-controlled diuresis, resulting in less variability in hemodynamic parameters. In general, a loading dose ranged from 0.1 to 2.4 mg/kg was used, followed by a continuous infusion ranging from 0.05 to 0.2 mg/kg/hour (maximum 0.4 mg/kg/hour). Pharmacokinetic evaluations and clinical evidence indicate that a higher furosemide dose of 0.2 mg/kg/hour may be required for patients with decreased renal function. It is important to note that all of the patients included these studies were below 4 years old.

Bukley et al. [45] studied bumetanide infusion doses in 40 neonates and children (1.6 ± 2.6 years). The reported mean initial dose was 30 mcg/kg/h (range: 1 to 100 mcg/kg/hour) and the mean maximum dose was 50 mcg/kg/hour (range: 3 to 200 mcg/kg/hour); a complete safety analysis was lacking in this trial. In 2015, McCallister et al. [46] suggested a dose from 1 to 10 mcg/kg/h based on their retrospective study of 95 patients (median 0.2 years, range 0 to 15.7 years). Negative fluid balance was achieved in 76% of patients within 48 hours of initiation; of note, 60% of patients were receiving concomitant intermittent diuretics.

Miller et al. [47] reported the effect of continuous ethacrynic acid infusion at a median initial dose of 0.13 mg/kg/h and a maximum dose of 0.17 mg/kg/h in a retrospective pilot study in nine patients. Ricci et al. [48] conducted a clinical trial of 36 pediatric post-operative cardiac surgery patients (mean age: 135 ± 181 days), reporting a mean effective dose of 0.22 ± 0.13 mg/kg/hour. These authors recommended an initial rate is 0.1 mg/kg/hour, to be titrated to a maximum reported infusion rate of 0.5 mg/kg/hour. There have been no published studies on the use of torsemide continuous infusion in children.

Congenital Heart Surgery

Fluid overload is common following congenital heart surgery, due to a combination of fluid resuscitation (intra- and postoperatively), hemodynamic instability, repair of blood loss on the day of surgery, postoperative acute kidney injury (around 50%), and systemic inflammation after cardiopulmonary bypass [49]. Fluid overload in the early postoperative period is associated with delayed sternal closure, longer ICU stay, prolonged inotrope and ventilation needs, and higher mortality and morbidity [50]. Post-cardiac surgery cases with an open sternum require aggressive volume removal to permit sternal closure. A recent systematic review and meta-analysis suggests that postoperative fluid overload is significantly linked to elevated risk of prolonged hospital stay, acute kidney injury, and mortality in pediatric patients undergoing cardiac surgery [51]. The main treatment for these patients is diuretic therapy. Furosemide is typically introduced when fluid overload exceeds 10% of basal body weight. However, recent studies suggest that fluid overload as low as 5% may be associated with poorer clinical outcomes [51]. There is increasing interest in low dose (3 mg/kg) aminophylline [52] and fenoldopam [53] as they seem to improve diuresis in combination with furosemide and reduce urinary acute kidney injury biomarkers. Onder et al observed in a retrospective chart review (200 patients) that the intraoperative use of aminophylline was more effective than furosemide in reversal of oliguria in the early postoperative period. The aminophylline group also required less renal replacement therapy [54]. However, a prospective randomized trial done by Axelrod et al in 2015 found no effect of aminophylline to prevent acute kidney injury in children recovering from cardiac surgery performed with cardiopulmonary bypass [55].

A common complication of protracted furosemide following cardiac surgery is the development of a contraction alkalosis which is thought to delay weaning from the respirator in some cases. Lopez et al recently showed that addition of a 2-day oral course of acetazolamide augmented diuresis and reduced serum bicarbonate and pCO_2 [56].

Acute Lung Injury

Both ARDS and acute lung injury (ALI) present with an increase in pulmonary vascular permeability due to regional endothelial damage [57]. Several studies show association between fluid overload and worse respiratory outcomes [58] [59]. In the Fluid and Catheter Treatment Trial (FACTT) [60] published in 2006, adults with ALI were randomized to a conservative versus liberal fluid management. The conservative strategy improved lung function and decreased the duration of mechanical ventilation without increasing non-pulmonary organ failure. Valentine et al. [59] demonstrated that increased fluid balance at day 3 in children with ALI was independently associated with fewer ventilator-free days but not with mortality. Silversides et al. conducted a systematic review and meta-analysis of this issue and found that patients with ARDS, sepsis, or SIRS (both adults and children) managed with early reduction of volume overload had increased ventilator-free days and decreased ICU stay compared with standard care; the effect on mortality was uncertain. Larger trials will be needed to optimize fluid strategies for managing acute pulmonary injury in children [61].

Traumatic Brain Injury/Cerebral Edema

Traumatic brain injury (TBI) might elicit a different response to fluid overload than the acutely injured lung, as recently described by Stulce et al [62]. This retrospective chart review of 138 patients with severe TBI demonstrated fluid overload (>10%) on day 10, but this did not contribute to mortality, longer ventilation time, increased risk of acute kidney injury, or increased stay in intensive care. In the absence of lung injury, fluid balance in severe traumatic brain injury relies on two mechanisms: first, the state of blood-brain barrier function and extracellular fluid kinetics [63] and, second, the severity of neurogenic pulmonary edema [64]. Thus, the risks of fluid overload may be more complex in isolated TBI [65].

Ascites

Independent of its cause, diuretics have a role in mobilizing moderately severe ascitic fluid which cannot be managed by salt restriction alone. Because of high aldosterone levels in patients with ascites, Bavdekar suggests oral furosemide (0.5–1.0 mg/kg twice daily) combined with spironolactone (1–3 mg/kg daily) to achieve net negative fluid balance of about 10 ml/kg/day. Spironolactone should be increased gradually every 3–5 days to reach this target, but more aggressive diuresis tends to compromise GFR [66]. Sabri recommends starting with spironolactone alone (2–3 mg/kg daily for 4–5 days, then doubling the dose if needed) [67]. This approach takes note of the long half-life of spironolactone; onset of diuretic effect may be delayed for several days and peaks at 2 weeks. Sabri reserves furosemide (0.5–1.0 mg/kg) for those with suboptimal response [67].

Neonates

Premature (<30 weeks gestation) newborns commonly develop bronchopulmonary dysplasia, with a requirement for oxygen during periods of mild fluid overload; nearly 40% of such newborns are exposed to diuretics to optimize pulmonary function [68]. Case reports in adults suggest that very high doses of furosemide (>1 gram/day) may be associated with hearing loss. In 2018, a large multicenter study was conducted of 1220 premature newborns (gestational age = 23–29 weeks) with exposure to standard doses of furosemide (about 1–2 mg/kg/day) for more than 28 days to test for an effect of furosemide exposure on hearing loss [68]. After accounting for a wide range of other possible risk factors (including comorbidity severity), some degree of hearing loss was noted in 14% of babies exposed to furosemide, compared to 10% among those who never received furosemide. However, this difference was not statistically significant.

Chemotherapy Protocols

In many standard chemotherapy protocols, hyperhydration (twice maintenance rate of intravenous fluid) is commonly used to induce high urinary flow rates to minimize direct toxicity of chemotherapeutic agents (e.g., cisplatin). However, hypoalbuminemia, kidney infiltration by leukemic cells, AKI, or tumor lysis syndrome from high tumor burden may compromise renal excretion of the fluid load. In this setting, intermittent loop diuretic (e.g., intravenous furosemide 0.5–1.0 mg/kg every 6 hours) is commonly used to target a urinary flow rate of >0.5 ml/kg/hr. In the setting of acute kidney injury, higher doses of furosemide can be given at increased dosing intervals (e.g., 2–4 mg/kg every 12 to 24 hours).

Acetazolamide can be used to hasten and or enhance urinary alkalinization during chemotherapy. During a period of intravenous sodium bicarbonate shortage in North America, several groups of adult oncologists compared various protocols for alkalinization of the urine during high dose methotrexate treatment [69]. They found that the time to alkalinization (15 hours) using a standard $NaHCO_3$ infusion of 250 meq $NaHCO_3/m^2$/day) could be achieved with an infusion containing less $NaHCO_3$, when oral acetazolamide was added to inhibit proximal tubular carbonic anhydrase and spill some of the filtered load of bicarbonate into the distal nephron. They reasoned that the latter approach might not be sustainable for 3 days (to allow complete methotrexate excretion) but that additional oral $NaHCO_3$ supplementation might suffice at that stage.

Adapting these observations to children, a practical protocol for timely alkalinization of the urine ($pH > 8.0$) prior to chemotherapy is as follows:

Infusion of 0.45% NaCl containing 75 meq/L $NaHCO_3$ at twice maintenance rates (3 L/m^2/day) plus acetazolamide (200 mg/m^2) at the outset. Intravenously, acetazolamide acts within minutes and alkalinizes the urine for 4–5 hours; if given orally, acetazolamide acts within 60–90 minutes and lasts 8–12 hours. By lowering the proximal tubular threshold for bicarbonate, addition of acetazolamide establishes early urine $pH > 8.0$ (to prevent obstructive methotrexate crystallization in distal tubules) and allows timely chemotherapy.

Kidney Transplantation

At the time of kidney transplantation, particularly in smaller recipients, large fluid volumes are administered to expand the central venous volume prior to unclamping and assure blood pressures sufficient to perfuse the adult allograft. In the first post-op day, additional positive fluid balance may be needed to compensate for "third-spacing." At 48 hours, most recipients have been fluid overloaded by 10–20% of preoperative body weight. Gradual repair of volume load is then usually managed by allowing the renal allograft to excrete the fluid load without full replacement. Whenever possible, diuretics are avoided since over-diuresis might risk sub-optimal renal perfusion. However, in the setting of delayed graft function or excessive fluid overload, a diuretic may be needed. Since the fresh renal allograft appears to be unusually responsive to loop diuretic, most transplant physicians use furosemide, but start at greatly reduced doses (e.g., 0.05–0.1 mg/kg/dose).

Prolongation of Urine Output in End-Stage Renal Disease

High dose loop diuretics have been used in oliguric dialysis patients to increase urine output, diminish the need for aggressive fluid removal during hemodialysis or peritoneal dialysis sessions. In a North American study of oliguric adult patients on peritoneal dialysis, Bargman et al reported that for each 250 ml of urine/day, the relative risk of death was decreased by 36% [70]. Lamarche et al studied 11 oliguric adults on peritoneal dialysis and found that a single oral dose of furosemide (500 mg) increased mean urine volume from 420 ml to 800 ml [71]. The International Paediatric Peritoneal Dialysis study examined residual renal function in children during the first year of peritoneal dialysis and noted an 80% decrease in the risk of developing anuria among those who were treated with a loop diuretic [72]. Shen et al. studied decline of renal function in the first year of peritoneal dialysis in 66 children and noticed a modest delay

(2 months) in the loss of urine output among those on diuretics [73].

Nonrenal Applications of Acetazolamide

Aside from its effects on the renal proximal tubule, acetazolamide is used in the management of glaucoma to reduce intraocular pressure. Carbonic anhydrase in the ciliary body of the eye generates the bicarbonate-rich fluid which is transported into the anterior chamber. Thus, acetazolamide reduces intraocular pressure by inhibiting aqueous humor production [50]. Interestingly, fluid shifts during hemodialysis may induce acute angle closure glaucoma in susceptible individuals [74], making it reasonable to consider single pre-dialysis doses of acetazolamide in this setting. However, studies in children for this unusual application are lacking. In the brain, acetazolamide reduces excessive intracranial pressure by blocking carbonic anhydrase in the choroid plexus, reducing production of cerebrospinal fluid [74]. In papilledema complicating growth hormone therapy, doses of 10–25 mg/kg/day, divided 3–4 times doses of 15–25 mg/kg/day (divided three or four times daily) typically reduce intracranial pressure over days to weeks and may be sustained for months [75]. Care must be taken to correct acidosis and avoid over-diuresis during this period.

Diuretic Use in Calcium Nephrolithiasis

HCTZ acts on DCT to block NaCl cotransporter, subsequent volume contraction induces increased sat reabsorption on TAL, hyperpolarizing electropositive lumen and driving calcium reabsorption through paracellular channels to produce hypocalciuria. A similar effect causes hypocalciuria in Gitelman syndrome vs Bartter syndrome where TAL reabsorption of salt is compromised, causing hypercalciuria. These effects provide the rationale for the use of HCTZ in individuals with hypercalciuria and kidney stones. Hydrochlorothiazide consistently reduces urinary calcium in children [76]. Liern reported that the relative risk of recurrent stone formation (3.3), episodes of hematuria (2.5), and osteopenia (3.0) is increased among those with hypercalciuria. Interestingly, thiazides reduce the risk of recurrent nephrolithiasis even when urinary calcium is within the normal pediatric [77] or adult ranges [78]. However, long-term success with this strategy is undercut by poor adherence. Although hydrochlorothiazide (0.5 mg/kg twice daily) reliably decreases urinary calcium, long-term nonadherence is reported in one-third of patients and hypercalciuria recurs in 44% [79].

SGLT2 Inhibitors in Diabetic Nephropathy

The gliflozins exert both cardioprotective and renoprotective effects in patients with diabetic nephropathy and it now appears that these benefits may extend to nondiabetic forms of heart and kidney disease as well. By inhibiting sodium/glucose reabsorption in the proximal convoluted tubule, increased solute is delivered to the macula densa, inducing constriction of the afferent arteriole, and dropping intraglomerular pressure [80]. A hemodynamic effect that reduces GFR slightly in the first weeks is followed by attenuation of progressive renal insufficiency that becomes evident by the end of the first year [80]. Cardiorenal protection is thought to occur, in part, by the reduction of central volume achieved through sustained diuresis and reduction in blood sugar; systolic blood pressure typically falls by 3–5 mmHg. Most clinical trials indicate that the renoprotective effects are additive to those of ACE inhibitors [81]. However, in some patients, concurrent diuretics may have to be reduced or curtailed to avoid excessive volume contraction during gliflozin therapy.

At present the gliflozins have not been approved for individuals <18 years old. However, since the early stages of diabetic nephropathy begin in childhood, there will inevitably be interest in use of these drugs in young people. Expertise from pediatric nephrologists (about the diuretic effects) and from pediatric endocrinologists (about effects on glycemic control and ketoacidosis) will be essential in learning how to apply these drugs safely in children.

Dosing and Pharmacokinetic Properties of Commonly Used Diuretics in Pediatrics (Table 2)

Table 2 Diuretic pharmacokinetics

Diuretic	Onset	Peak	Duration	Half-life	ESRD	Reference
Acetazolamide po	1–1.5 hours	2–4 hrs	18–24 hrs	2.4–5.8	Long T1/2	[31]
Acetazolamide iv						
Canagliflozin po	<24 hrs	1–2 hrs	24 hrs	11 hrs	Adjust, eGFR<45	–
Empagliflozin po	<24 hrs	1.5 hrs	24 hrs	12.4 hrs	Adjust, eGFR <45.	–
Dapaglifozin po	<24 hrs	2.0 hrs	24 hrs	12.9 hrs	Long T1/2	–
Mannitol iv	Diuresis 1–3 hrs			1.5–2.5 hrs	T1/2 = 6–36 hrs	[31]
	ICP 15-30 min		1.6–6 hrs			
Furosemide po	30-60 min	1–2 hrs	6–8 hrs	0.5–2.0 hrs	T1/2 = 9 hrs	[9]
Furosemide iv	15 min	0.5 hrs	2 hrs	0.5–2 hrs	T1/2 = 9 hrs	
Bumetanide po	0.5–1.0 hours	1–2 hrs	4–6 hours	1 hr	50% hepatic	
Bumetanide iv	2–3 min	15–30 min	2–3 hours	6–15 hrs (neonates)		[94]
				2.5 hrs <2mo		
				1.5 hrs 2-6mo		
				1.-1.5 hrs adults		
Hydrochlorothiazide po	2 hrs	4–6 hrs	6–12 hrs	6–15 hrs	Long T1/2	[96]
Chlorthalidone po	2.6 hrs	2–6 hrs	24–48 hrs	14–20 hrs	Long T1/2	[98]
Metolazone po	1 hr		>24 hrs	8–15 hrs	Long T1/2	[99]
Amiloride po	2 hrs	6–10 hrs	24 hrs	6–9 hrs	Long T1/2	[17]
Spironolactone po		2.6–4.3 hrs	2–3 days	1–2 hrs	Hepatic	[92]
Tolvaptan po	2–4 hrs	4–8 hrs	<24 hrs	3 hrs	Long T1/2	[101]

Abstract

Pierre Rayer first described the cystic degeneration of the kidneys in 1841. Later Felix Lejars formally coined the term "polycystic kidney disease" in 1888. However, to date, autosomal dominant polycystic disease (ADPKD) is still a disease without cure despite representing the most common monogenic cause of renal failure. Research accelerated after *PKD1* and *PKD2* were identified in 1994 and 1996, several underlying mechanisms that cause ADPKD have been elucidated, and major advancements in diagnosing, prognosticating, and understanding the natural course of the disease resulted in the approval of the first likely disease-modifying treatment in vasopressin V_2 receptor antagonists.

Awareness is growing that the clinical course of ADPKD begins in childhood and the wind of change in the management of more nephron-protective strategies and lifestyle modifications with early referral and follow-up are evolving. This chapter aims to deeply describe the genetic background, pathophysiology, clinical manifestations, and main therapeutic options including the future perspective. The currently accepted views on the optimal management in childhood ADPKD with regard to ethical and practical aspects will be summarized.

Introduction

Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary kidney disease, affecting 1 in 1000 individuals of all races and ethnicities and accounting for nearly 5% of end-stage kidney disease (ESKD) [121, 152]. The cardinal manifestation of ADPKD is bilateral progressive cystic dilation of renal tubules with eventual compression of normal renal parenchyma, kidney enlargement, and loss of renal function, with approximately half of affected individuals reaching ESKD by 60 years of age. It is a systemic disease, with extrarenal manifestations including hepatic, splenic, and pancreatic cysts, vascular dysfunction and early onset hypertension, and intracranial aneurysms. Although historically considered a disease of adults, it has become clear in recent decades that ADPKD has important clinical manifestations in childhood and in some cases as early as in utero [36]. Early identification of high risk patients is critical to allow timely intervention to alter long-term prognosis. The purpose of this chapter is to review the genetics, pathophysiology, clinical manifestations, diagnostic considerations, and potential therapies associated with pediatric ADPKD.

Genetics, Structure, and Function of Mutated Proteins

ADPKD is a heterogenetic disorder most often caused by mutations in the *PKD1* gene located on chromosome 16p13.3 encoding polycystin-1 (PC1) (~78% of cases) or in the *PKD2* gene located on chromosome 4q22 encoding polycystin-2 (PC2) (~15% of cases) [117]. Many years were spent looking for a "third locus" with recent studies identifying ADPKD due to mutations in *GANAB* (~0.3%), *DNAJB11* (~0.1%), and ALG9 ([114, 32, 7]).

PKD1 is a very large gene, spanning 53 kb of genomic DNA with 46 exons including a 14.5 kb transcript (International Polycystic Kidney Disease Consortium [113]). A region of the 5′ end of *PKD1* from exons 1 to 33 is duplicated six times approximately 15 Mb proximal to the *PKD1* gene on chromosome 16. The high sequence homology of these six pseudogenes (P1-P6) to *PKD1*, nearly 100% in exonic sequence, complicates genetic sequencing and requires locus-specific long-range PCR products to specifically amplify *PKD1* [118]. The gene encodes the large novel 4304–amino acid 460 kD protein product polycystin-1 (PC1) whose precise function is unknown. PC1 is an integral membrane protein with a large extracellular N-terminal domain (~3000 amino acids), 11 transmembrane domains, and a C-terminal cytosolic domain of 200–225 amino acids. The extracellular domain of PC1 contains a physiologically important G-protein-coupled receptor proteolytic site. The cytoplasmic tail of PC1 has a coiled-coil motif and two nuclear loop localization sequences. In addition to the GPS cleavage site, cleavage of PC1 at the C-terminal tail releases a soluble 35 kD fragment [26]. The carboxy terminal domain of PC1 undergoes proteolytic cleavage, and nuclear translocation of the PC1 carboxy-terminus plays a role in regulating gene expression. These features suggest that PC1 is a large, multifunctional molecule involved in carbohydrate motif recognition, ligand binding, and Ca^{2+} regulation. It may engage in cell-cell and/or cell-matrix interactions which regulate signal transduction pathways mediated by cell surface protein–protein interactions or directly participate in regulating transcriptional programs through the cleaved cytoplasmic tail. PC1 is expressed in multiple tissues including kidney, liver, pancreas, intestine, and cerebral blood vessels, all sites of pathologic changes in ADPKD, as well as in the lung, testes, and other tissues. More than 1250 pathogenic *PKD1* variants have been identified, spread throughout the gene, of which up to 70% are unique to a single family. The *TSC2* and *PKD1* genes lie adjacent to each other in a tail-to-tail orientation on chromosome 16 at 16p.13.3. Deletions inactivating both genes lead to the *TSC2/PKD1* contiguous gene syndrome which is associated with early onset (usually in infancy) severe cystic kidney disease with features of tuberous sclerosis and high risk for rapid loss of kidney function in childhood and early adulthood [120].

PKD2 has been linked to chromosome 4q13-q23 [107]. It expresses a 5.4 kb mRNA which encodes a 968–amino acid polypeptide, polycystin-2 (PC2) [94]. PC2, also called TRPP2, is a calcium–permeable nonselective cation channel [61]. PC1 and PC2 are thought to interact through their C-terminal tails, and the resulting complex has been proposed to regulate intracellular calcium influx [57]. Of more than 250 known *PKD2* pathogenic variants, spread throughout the gene, half are unique.

Mutations in *PKD1* and *PKD2* produce similar phenotypes. However, the natural course of ADPKD is significantly influenced by the causative gene. Specifically, *PKD1* mutations are associated with larger kidneys with more cysts as compared to *PKD2*; however, the rates of cyst growth do not differ, suggesting that PKD1 is more severe because cysts develop earlier and not because they grow faster [3, 63]. Mutations in *PKD1* are thus not surprisingly associated with earlier onset of ESKD (58 vs. 79 years) than with *PKD2* mutation [30]. Moreover, among patients with *PKD1* mutations, ESKD is reached earlier with truncating mutations vs non-truncating mutations (55.6 vs. 67.9 years).

Recently mutations in other genes including *GANAB*, *DNAJB11*, and *ALG9* have been associated with ADPKD. *GANAB,* which localizes to chromosome 11q12.3 with genomic size 21.9 kb, has been proposed to account for ~0.3% of ADPKD and encodes the catalytic subunit of glucosidase II (GIIα). It was identified as a candidate gene by whole exome sequencing in several families with ADPKD whose routine genetic screening was not informative [114]. A unique feature in many of these families was the lack of significant kidney enlargement or dysfunction despite cystic kidney disease. Furthermore, there was a high prevalence of hepatic cysts and polycystic liver disease (PLD). Through combined genetic human and cellular studies, Porath et al. demonstrated that mutations in *GANAB* caused ADPKD and autosomal dominant polycystic liver disease (ADPLD) and that loss or reduction of GIIα is associated with maturation and localization defects in PC1 and PC2.

Mutations in *DNAJB11*, located at chromosome 3q27.3, have also been shown to cause atypical ADPKD [32] with non-enlarged kidneys with multiple small cysts and significant interstitial fibrosis, with evolution to renal insufficiency after the sixth decade. *DNAJB11* encodes one of the main cofactors of the endoplasmic reticulum chaperone BiP, a heat-shock protein required for efficient protein folding and trafficking. It has been proposed that *DNAJB11*-related disease induces a hybrid phenotype with features of ADPKD from PC1 maturation defects and autosomal dominant tubulointerstitial kidney disease due to intra-cytoplasmic retention of tubular proteins like uromodulin.

In a cohort of genetically unresolved polycystic kidney and liver disease, Besse et al. [7] identified *ALG9* mutations as another rare source of atypical ADPKD. *ALG9* encodes an endoplasmic reticulum enzyme which builds N-glycans, and inactivation is associated with impaired PC1 maturation. Nearly 90% of carriers of *ALG9* mutations over age 50 years have multiple kidney cysts. However, the spectrum of cystic renal and liver involvement is variable. More comprehensive studies are needed to fully characterize the natural course of these rare forms of ADPKD.

Finally, it is important to consider the impact of combined and hypomorphic genetic variants in the ADPKD phenotype. Although fully penetrant biallelic pathogenic variants in *PKD1* or *PKD2* are predicted to be incompatible with life, biallelic hypomorphic *PKD1* mutations or the combination of a classical and an ultra-low penetrant PKD1 mutation can cause severe early onset ADPKD [39, 104, 118, 145]. Digenic disease with variants in *PKD1* and *GANAB* has also been identified in a child with early onset ADPKD [146]. Severe ADPKD may also occur with combined transmission of mutations in *PKD1* or *2* and other cystic nephropathy genes such as *HNF1β* or *PKHD1* [5, 6].

Pathophysiology of Kidney Cyst Formation

ADPKD is characterized by kidney cysts that gradually form and increase in number and size. Kidney cysts may arise from any segment of the nephron, most typically the distal nephron and the collecting duct, but originate from only about 1% to 5% of nephrons in total. Unlike autosomal recessive polycystic kidney disease (ARPKD), in which the cystic dilatations are fusiform in nature and remain in connection with the tubular lumen, in ADPKD the enlarging cysts ultimately detach from the tubular lumen and urinary space. This eventually leads to marked enlargement of the kidneys with vascular remodeling and interstitial fibrosis in advanced ADPKD. Although every cell in the kidneys of ADPKD patients carries the same monoallelic genetic germline mutation, only about 100 cysts per kidney are formed in a lifetime. Several hypotheses are suggested to explain this phenomenon [64, 68] (Fig. 1). It has been suggested that an additional somatic mutation in the second wild-type allele, as a recessive cellular mechanism, leads to cyst formation later in life, that is, the "second hit hypothesis." This is supported by a recent next-generation sequencing study that demonstrates somatic *PKD1* and *PKD2* mutations in the epithelium of 90% of cysts measuring over 1.5 cm [134, 156]. More recently, the importance of the dosage of functional PC protein below a critical threshold (20–30% of normal values) has been described as the "threshold hypothesis." This hypothesis is influenced by the type of mutation(s) and local stochastic factors [69, 81, 109]. In addition, the "third hit hypothesis" proposes the role of inflammation, ischemia-reperfusion, nephrotoxicity, and crystal deposition as additional triggers to induce cyst growth [62, 133, 137, 151]. Finally, the "snowball effect" suggests that local and mechanical effects of the cyst can disrupt flow in the adjacent tubule segments as well as in blood and lymphatic vessels [83]. Indeed, cysts that developed from the collecting duct in inner medulla have the potential to destroy the function of hundreds – if not thousands – of upstream nephrons that ordinarily drain

Fig. 1 Molecular mechanisms leading to cystogenesis in ADPKD. Left: The transformation of a tubular cell to a cystic cell requires a somatic mutation ("second hit," marked with an asterisk) to complement the germline mutation (marked with x), the decline of functional PC1 levels ("threshold hypothesis" represented by the graph), and/or renal stress factors ("third hit" represented by the lightning). Right: Several cellular alterations are required to generate cystic cells (marked in pink boxes). As the polycystins are expressed in the cilia, altered ciliary function including reduced ciliary Ca^{2+} signaling is proposed to trigger cyst formation. PC1 and PC2 also affect Ca^{2+} signaling by regulating IP$_3$R and STIM1. Reduced intracellular Ca^{2+} levels will also lead to enhanced cAMP (through less suppression of AC6), which in turn triggers enhanced Cl$^-$-driven fluid secretion and enhanced mTOR activity. Altered mTOR and Wnt signaling can trigger enhanced proliferation by stimulating STAT3-mediated transcription. Altered Wnt signaling will also influence cell polarity. Finally, ADPKD cells are also characterized by metabolic reprogramming involving enhanced glycolysis and reduced TCA. Several possible chemical modulators that are under investigation as drugs to suppress ADPKD progression are shown in the pathways they target. 2DG: 2-deoxy-D-glucose; AC6: adenylate cyclase 6; AMPK: 5′ adenosine monophosphate-activated protein kinase; cAMP: 3′,5′-cyclic adenosine monophosphate; CFTR: Cystic fibrosis transmembrane conductance regulator; EGFR: epidermal growth factor receptor; Gi: Gi protein alpha subunit; Gs: Gs alpha subunit; IP3R: Inositol 1,4,5-trisphosphate receptor; MAPK/ERK: mitogen-activated protein kinase/extracellular signal-regulated kinase; mTOR: mechanistic target of rapamycin; PC1: polycystin 1; PC2: polycystin 2; SSTR: Somatostatin receptor; STAT3: Signal transducer and activator of transcription 3; STIM1: Stromal interaction molecule 1; TCA: tricarboxylic acid cycle; TSC1/2: tuberous sclerosis 1/2; V2R: Vasopressin receptor 2; Wnt: Wingless/Int-1 Wnt pathway

into the tubule arcade served by the cystic collecting duct [58].

The mechanism(s) of cystogenesis in ADPKD are complex and not fully elucidated (Fig. 1). Loss-of-function of the polycystins modifies the regulation of multiple signaling pathways, including intracellular Ca^{2+} homeostasis, mechanistic target of rapamycin (mTOR) activation, and 3′-5′-cyclic adenosine monophosphate (cAMP) levels, ultimately resulting in abnormal ciliary structure or function, increased cell proliferation, altered apoptosis and autophagy, enhanced fluid secretion, abnormal cell-cell/matrix interactions, and alterations in cell polarity. PC1 and PC2 can both be found in the primary cilium, which is an antenna-like structure present on most types of mammalian cells, and therefore ADPKD is considered a ciliopathy. Initially the PC complex was thought to function as a sensor of laminar flow, impacting intracellular Ca^{2+}-flux upon stimulation [37, 88]. However, this hypothesis has recently been questioned and remains controversial. While reduced ciliary Ca^{2+} influx after mechanical stimulation has long been postulated as one of the primary events in cystogenesis, recent evidence shows little Ca^{2+} influx into cilia under physiological conditions, and ciliary Ca^{2+} concentration does not change upon mechanical bending of primary cilia in multiple cell types.

It has been further suggested that the abnormal Ca^{2+} signaling in ADPKD could result from altered PC2 function as an ER Ca^{2+}-release channel. Indeed, at the ER, PC2 is thought to regulate intracellular Ca^{2+} release through interactions with the inositol 1,4,5-trisphosphate receptor (IP_3R), the ryanodine receptor, and stromal interaction molecule-1 (STIM1). PC2 enhances Ca^{2+} release from the ER by stimulating the activity of the IP_3R, whereas PC1 inhibits this process by reducing PC2-IP_3R interactions via a mechanism involving STIM1 and the PI3K/AKT pathway [19, 93]. At the plasma membrane, PC1 regulates cell adhesion and cell matrix composition via regulation of planar cell polarity through wingless/integrated (Wnt) signaling, increased fluid secretion in cysts driven by the cystic fibrosis transmembrane conductance regulator (CFTR), and activation of proliferative pathways affecting intracellular signaling, for example, mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (ERK), signal transducer and activator of transcription 3 (STAT3), and mTOR. An additional hallmark of ADPKD is the alteration of cell proliferation of cystic kidney epithelial cells. Mutations in the PKD genes have been observed to increase mTOR activity by the inhibition of the TSC1/TSC2 complex via a mechanism that includes the cAMP-dependent B-Raf/ERK pathway [143]. Recently, aberrant aerobic glycolysis has been observed in PC1-deficient epithelial cells which triggers a metabolic reprogramming of the cell similar to cancer cells (the "Warburg effect"). In vitro characterization of the metabolomic profile of PC1-deficient mouse tissue shows an important metabolic shift with increased glycolysis, glutaminolysis, and reduced tricarboxylic acid cycle (TCA). In vivo analysis of 13C-glucose tracer in murine models of PKD has highlighted an increased glucose uptake and lactate production with increasingly severe disease manifestation. Furthermore, the administration of the non-metabolizable glucose analogue 2-deoxy-D-glucose (2DG) slows down disease progression in *PKD1* −/− cells [103, 112, 119]. Although these metabolic alterations seem to play a central role for the disease progression, the mechanisms behind it remain unknown.

Structural Kidney Disease: Implications for Symptoms and Disease Progression

The clinical phenotype of ADPKD can vary widely, especially in childhood. We know however that progressive structural kidney disease occurs from early in life and far in advance of any signs or symptoms. Recent studies have therefore highlighted the importance of total kidney volume (TKV) as an early and important marker of disease progression in ADPKD prior to any detectable change in glomerular filtration rate (GFR).

Cohort studies in children at-risk for ADPKD (one parent known to have ADPKD) demonstrated that despite normal kidney function, affected children have larger kidneys which grow faster than those of unaffected children and that affected children with hypertension have larger kidneys than those with normal blood pressure [15, 41, 43]. Studies utilizing MRI in ADPKD adults described a direct correlation between TKV and hypertension or proteinuria and an inverse correlation between TKV and estimated GFR (eGFR) [23, 60, 102]. In affected adults, height-corrected TKV over 600 mL/m predicts functional decline to chronic kidney disease stage 3 within 8 years [24].

Serial MRI has confirmed the progressive increase in TKV and total cyst volume (TCV) in children with ADPKD [16]. Higher TKV, TCV, and fractional cyst volume (the percent of TKV occupied by cysts), as well as increase in cyst volume over time have been observed in hypertensive as compared to normotensive children with ADPKD. The annual increase in TKV observed over a five-year study period was 7.4% per year overall and 8.1% per year in young adult subjects (18–21 years of age). This growth rate was higher than that observed in ADPKD adults (5.3% per year, [60]) and may reflect the impact of fibrosis in later stage disease. Thus the value of increasing TKV as an early marker of disease progression, particularly in childhood, cannot be understated.

Renal Manifestations

Hypertension. With advances in renal replacement therapy, cardiovascular disease is now the leading cause of death in ADPKD. Onset of hypertension prior to 35 years of age is a concerning prognostic factor in adults with ADPKD and has been associated with faster progression to ESKD compared to patients with later onset hypertension [48]. Hypertension occurs with increased frequency in children with ADPKD, with an overall prevalence of 20–40%, significantly higher than in the general pediatric population, and increasing in prevalence with age [41, 90, 91, 125]. Of ADPKD children with normal blood pressure followed at a tertiary care center for a five-year period, 52% of children with baseline blood pressure in the 75th to the 95th percentile and 28% of children with blood pressure below the 75th percentile but with 10 or more kidney cysts developed systemic hypertension [15].

These observations are worrisome, as studies in the general population support tracking of blood pressure from childhood to adulthood and suggest that elevated blood pressure in childhood may initiate chronic alterations in the cardiovascular system such as increased left ventricular mass index and premature atherosclerosis which increase long-term risk of cardiovascular morbidity and mortality [4, 28]. Moreover, studies in both ADPKD children and adults demonstrate a consistent positive correlation between blood pressure and kidney size. This relationship is particularly strong in children and is consistent across both normal and elevated systolic and diastolic blood pressures [14]. Of particular concern, increased TKV and fractional cyst volume associated with hypertension in ADPKD children does not appear to be impacted by degree of blood pressure control nor use of angiotensin converting enzyme inhibition (ACEI) and is associated with decreasing eGFR over time, albeit within the normal range [15, 16].

24-hour ambulatory blood pressure monitoring (ABPM) is an important management tool in pediatric ADPKD. ABPM is more valid and reliable than casual blood pressure measurement [129], and ABPM values are closely associated with left ventricular hypertrophy in children [10] and with kidney disease progression or death in adults with chronic kidney disease [1]. Isolated nocturnal hypertension with normal daytime blood pressure has been reported in 16–18% of children with ADPKD [91, 125]. Such children would not otherwise be identified without the use of ABPM, and early detection of hypertension is critical to mitigate long-term morbidity and mortality.

The pathophysiologic mechanisms of hypertension in pediatric ADPKD are poorly understood, and it is often assumed that the pathogenesis is similar in children and adults (reviewed in [13]). It has been proposed that cyst expansion leads to compression of the renal vasculature with local ischemia/hypoxia and intrarenal activation of the renin-angiotensin-aldosterone system (RAAS) which then mediates cyst growth, fibrosis, and hypertension [21, 123]. In support of this theory, adult ADPKD patients were shown to have increased plasma renin activity and serum aldosterone concentrations in both the supine and upright positions in response to ACEI treatment as compared to matched controls with essential hypertension, with a significant decrease in renal vascular resistance in the ADPKD group after ACEI treatment [21]. Histologic studies have also localized angiotensinogen, renin, ACE, angiotensin II, and the AT1 receptor within cysts and dilated tubules in ADPKD kidneys [85]. However, a direct link between RAAS and kidney cyst growth has yet to be demonstrated. Other proposed mechanisms of hypertension in this condition include activation of the sympathetic nervous system [20, 53], which is also known to stimulate RAAS, and decreased nitric oxide production.

Kidney dysfunction. The association between impaired urinary concentrating capacity and extent of structural kidney disease in ADPKD has long been recognized in both adults [46] and children [41] but there are little data to support higher prevalence of polyuria, urinary frequency, or nocturnal enuresis in ADPKD children. While microalbuminuria has been demonstrated to be an important marker of progressive disease in adults [22], this has not been found in repeated cohorts in pediatric ADPKD [15, 17]. However, overt non-orthostatic proteinuria is suggestive of advanced disease in childhood. Declining GFR is a late feature of the disease attributed to glomerular hyperfiltration in remnant nephrons. Once adults with ADPKD manifest falling eGFR, a progressive decline of 4–6 mL/min per year is anticipated [75]. Children with ADPKD demonstrate glomerular hyperfiltration when compared to healthy controls [154]. When present, this finding is associated with faster decline in kidney function and higher rate of kidney enlargement over time [65]. Fortunately however the vast majority of children with ADPKD maintain kidney function within the "normal" range given these considerations.

Abdominal/flank pain. Approximately 10–20% of children with ADPKD complain of abdominal or flank pain [49], a rate which is comparable to the general pediatric population [79, 136]. Potential etiologies in ADPKD include cyst expansion particularly when associated with capsular irritation, cyst hemorrhage, cyst infection (often associated with fever), urinary tract infection (UTI), or urolithiasis. Severe chronic pain can also occur in the setting of significant kidney enlargement and may be associated with chronic early satiety and/or reflux symptoms. Tumors associated with ADPKD in childhood are exceedingly uncommon. Pain due to cyst rupture typically resolves within 2–7 days without needing intervention other than rest, analgesics, and adequate hydration. Management of chronic pain due to ADPKD should include a multidisciplinary pain team approach to support self-management skills and to avoid chronic narcotic use. Nonsteroidal anti-inflammatory drugs are often avoided in ADPKD due to potential impact on renal function.

Macroscopic hematuria. Macroscopic hematuria can occur in the setting of cyst hemorrhage, urolithiasis, or UTI. Passage of clots can be associated with urinary tract pain but this scenario is uncommon with cyst hemorrhage. Such gross hematuria is typically self-limited. Macroscopic hematuria has been associated with enlarged TKV in adult ADPKD ([47], [73]), and its occurrence prior to 35 years of age portends worse kidney survival in affected adults [31]. However, there is no evidence currently for a predictive association between macroscopic hematuria and long-term kidney outlook in childhood ADPKD [41, 127]. This issue requires further study.

Other urinary tract concerns. As in adults, studies have suggested an increased frequency of urinary tract infection in children with ADPKD [41]. The prevalence of UTI may be overestimated however as culture results are not always reported. In any case, children with ADPKD do not seem to be at particular risk for complicated UTI, thus evaluation and treatment should proceed per routine practice. Cyst infection can rarely occur in childhood, often in association with fever, ill appearance, increased inflammatory markers, and sterile pyuria.

Nephrolithiasis occurs in 20–35% of adults with ADPKD but appears significantly less common in children with ADPKD. Evaluation and treatment should proceed as per routine for children with nephrolithiasis.

Extrarenal Manifestations

Cardiac disease and vascular dysfunction. Children with ADPKD have increased left ventricular mass index (LVMI) as compared to healthy children even with equivalent blood pressure [160]. There is also good correlation between both systolic and diastolic blood pressure and LVMI in children with ADPKD [14]. Not surprisingly, hypertensive ADPKD children have higher LVMI than affected children with normal blood pressure [71]. However, children with ADPKD and blood pressure in the 75th to the 95th percentile also demonstrate an increase in LVMI which is comparable to that of hypertensive ADPKD children and is significantly higher than that of affected children with lower blood pressure [14]. These findings suggest that significant cardiovascular manifestations are already occurring early in children with ADPKD and even within normal range of blood pressure.

Cardiac valvular abnormalities have also been reported to occur with increased frequency in ADPKD. For example, mitral valve prolapse was described in 12% of children with ADPKD, as compared to 3% of healthy siblings [71]. More recent experience however suggests lower prevalence than historically described. Routine echocardiogram looking specifically for cardiac valve disease is recommended only in the setting of concerning cardiac exam.

ADPKD is also associated with chronic vascular dysfunction as assessed by flow-mediated dilation (FMD) and by pulse wave velocity (PWV) of large elastic (aorta and carotid) arteries [8, 78, 149]. Both of these measures are independent predictors of future cardiovascular events and mortality. A recent study in children and young adults with normal eGFR demonstrated that vascular dysfunction is an early finding in ADPKD, with affected participants demonstrating significant impairment in FMD and increase in PWV compared to healthy controls [98].

Cysts in other organs. ADPKD is associated with cysts in other organs such as liver, spleen, pancreas, and seminal vesicles. However, extensive cystic disease in these organs is rare in childhood ADPKD, and routine screening is not recommended [56]. Extensive cystic involvement of the liver and/or pancreas should raise consideration for atypical or alternate disease including *GANAB* mutation in the case of liver cysts or *HNF1β* with significant pancreatic involvement. ADPKD-associated liver cystic disease is reported to be more severe in women who have had multiple pregnancies and in postmenopausal women receiving estrogen therapy [128]. The effect of hormonal contraception on liver cystic disease in young women with ADPKD is not known.

Intracranial aneurysms (ICA). ADPKD is associated with a fivefold higher prevalence of ICA than in the general population. This risk is particularly increased in patients with a family history of PKD-associated ICA or subarachnoid hemorrhage (up to 10% of the general population with ADPKD; 22% with positive family history versus 6% with negative family history) [110]. PKD-associated intracranial aneurysms are extremely unusual in childhood and routine screening is not recommended.

Prenatal, Very Early Onset (VEO), and Severe ADPKD

With advances in imaging resolution and increased application of imaging techniques from prenatal life onward, there has been an increase in the incidental diagnosis of ADPKD in childhood. By prenatal imaging, ADPKD may be evident in the fetus as enlarged kidneys, abnormal kidney echogenicity with increased corticomedullary differentiation (in contrast to the decreased corticomedullary differentiation more typical of ARPKD, and/or discrete cysts). The family history should be carefully reviewed, and in cases where a diagnosis is not evident, sonographic screening of parents may reveal previously undiagnosed ADPKD (or other relevant cystic kidney disease of ARPKD) and discrete cysts. The mere detection of such prenatal imaging abnormalities does not necessarily portend poor outcome, as serial monitoring in childhood is often reassuring, with enlarged kidneys improving to normal size over early childhood [9]. However, when accompanied by signs of fetal kidney dysfunction such as oligoanhydramnios, a high level of concern is warranted. Occasionally, significant unilateral kidney cystic involvement is observed in childhood and can be mistaken for other cystic kidney conditions before progression to involve both kidneys occurs [42]. Although all individuals with ADPKD are expected to develop kidney cysts, there can be significant variability even within the same family.

Importantly however, a subgroup of children has more severe ADPKD than the classical course and may suffer ESKD in early childhood [41, 97, 127]. In the most severe cases, oligoanhydramnios can lead to pulmonary hypoplasia and death in the neonatal period. For surviving children, hypertension can be severe and require multidrug therapy, and features of chronic kidney disease may be present from infancy. The term “very early onset” (VEO) ADPKD is used to distinguish this group of affected children who are diagnosed before 18 months of age due to enlarged kidneys accompanied by hypertension, persistent proteinuria, and/or reduced eGFR. A well-matched case control study found that VEO patients were much more likely to develop hypertension and to progress to eGFR ≤90 mL/min/1.73 m^2 during childhood as compared to their non-VEO counterparts [97]. All cases of early ESKD occurred in the VEO group. The frequency of glomerular hyperfiltration was similar between the groups but occurred earlier in the VEO group. The term “early onset” ADPKD has been suggested to identify children diagnosed with ADPKD between 18 months and 15 years of age with enlarged kidneys accompanied by hypertension, proteinuria, and/or reduced eGFR [33]. As noted previously, more recent studies have elucidated the role of biallelic and digenic variants as contributors to severity of disease in VEO and severe ADPKD.

Diagnostic Considerations

Diagnostic criteria for ADPKD in adults have been extensively defined [25] but are less well-established in children. Clinical features that raise suspicion of ADPKD in adults include: multiple bilateral kidney cysts in the absence of manifestations suggestive of an alternate cystic kidney disease; cysts in other organs such as liver, seminal vesicle, pancreas; kidney or liver enlargement; early onset hypertension before 35 years of age; intracranial aneurysm; family history of ADPKD. It is important to obtain a detailed family history of cystic kidney disease and associated complications. The diagnosis of ADPKD in adults is typically confirmed by imaging, with genetic testing reserved for atypical cases or to exclude ADPKD in a potential kidney donor. The diagnosis is established in a proband when age-specific ultrasound or MRI criteria are met in the setting of a family history of a first-degree relative with ADPKD or with identification of a heterozygous pathogenic variant in one of the genes known to cause ADPKD. Teenagers and young adults have been included in some of the studies which established the imaging criteria for ADPKD, but the majority of participants were older adults. Pei et al. [105] suggested that for individuals aged 15–39 years with an affected first-degree relative, the presence of three or more (unilateral or bilateral) kidney cysts establishes a diagnosis of ADPKD. The positive predictive value for this criterion is 100% for both *PKD1* and *PKD2*. However, the sensitivity is lower for *PKD2* (70% vs. 94% for PKD1). By MRI, in individuals aged 16–40 years with an affected first-degree relative, the finding of more than 10 cysts is sufficient for diagnosis of ADPKD [106]. While the identification of kidney cysts is obviously supportive of the diagnosis within these parameters, an absence of cysts is less informative. Because mild structural kidney disease can be seen with incompletely penetrant, non-truncating *PKD1* variants or pathogenic variants in other ADPKD-related genes, normal kidney imaging does not exclude the diagnosis of ADPKD in at-risk individuals under 40 years of age [105].

These guidelines therefore have important implications for elective screening of at-risk individuals, and the potential for a non-informative result should be reviewed with families before pursuing routine imaging screening in at-risk children.

The imaging criteria for diagnosis in earlier childhood are not as clearly established. Some have suggested that in the setting of an affected first-degree relative, a single kidney cyst is sufficient for diagnosis [56] while others have proposed that bilateral kidney cysts be required [115]. There are no established imaging-based criteria for diagnosis of ADPKD in children without a family history. In this setting, diagnosis is largely based on clinical phenotype with genetic screening available for confirmation. In the absence of known family history, it can be informative to obtain imaging on parents following the diagnosis in a child. De novo mutations can occur. As previously noted, genetic testing may also be particularly helpful in atypical presentations or in sporadic ADPKD without clear family history.

Regarding choice of imaging modality for diagnosis in childhood, TKV assessment appears to correlate well between MRI and ultrasound in childhood [16] but MRI is preferred when very accurate assessment of TKV is needed, as in the research setting. The correlation between standard ultrasound and MRI diminishes with more progressive structural disease due to both the user-dependent nature of sonographic kidney measurement and the invalid assumption of relatively normal kidney architecture using the ellipsoid formula to estimate sonographic TKV. However, the clinical utility of MRI for routine imaging may be limited in very young children due to cooperation and motion artifact. CT is also accurate for assessing structural kidney disease, but repeated CT is often avoided due to risks of radiation exposure. More recent studies suggest that 3D ultrasound with manual contouring may represent an alternative to MRI with improved accuracy versus 2D ultrasound in early ADPKD [11, 55].

Screening in asymptomatic at-risk minors. Before pursuing routine sonographic or genetic screening for asymptomatic minors at-risk for ADPKD due to known family history, a thoughtful discussion with parent(s) and patient (as developmentally appropriate) is warranted. As application of disease-specific therapies (e.g., pravastatin, tolvaptan; see "Treatment" section) evolves in pediatric ADPKD, more widespread routine screening is anticipated. However, families must understand the limitations, including the imperfect nature of radiographic screening to fully exclude ADPKD in childhood, and implications for psychological adjustment and insurability, and the minor should be involved in the decision to screen as developmentally able. In the absence of elective radiographic/genetic screening in asymptomatic minors, annual assessment for nephromegaly, hematuria/proteinuria, and hypertension is recommended [56]. In cases where screening is not pursued, parents should be counseled regarding their responsibility to inform their children of disease risk when they reach the age of majority.

Preimplantation genetic diagnosis (PGD). PGD for ADPKD is possible if a conclusive genetic mutation has been identified in the affected parent. In addition to the ethical implications, discussion of PGD should consider that although common, ADPKD in its typical form is not usually life-threatening or even life-limiting. However, specific genetic mutations (biallelic disease or truncating *PKD1* mutations) may have bearing in such discussions. One study found that while nearly 70% of affected CKD and ESKD participants felt that PGD should be offered to ADPKD patients, less than 20% of these same participants would consider termination of pregnancy for a diagnosis of ADPKD [131].

Differential diagnosis. The differential diagnosis of ADPKD includes numerous cystic kidney diseases. Historically ADPKD diagnosed in childhood was often mistaken for ARPKD due to the age at presentation; this was particularly common with VEO ADPKD. Prenatally, both conditions can be associated with enlarged echogenic kidneys and can be accompanied by oligoanhydramnios if significant kidney dysfunction is present. It has been suggested that increased corticomedullary differentiation (CMD) is more common in ADPKD while decreased CMD occurs more commonly with ARPKD. Macrocysts are more common in ADPKD but can occur with either condition; these often resolve early in life to a more typical microcystic appearance in ARPKD. Both conditions can occur in neonates or infants with severe hypertension, nephromegaly, and kidney failure. In the setting of an apparently negative family history, screening of parents for cystic kidney disease may be helpful. Sonographic imaging of the liver may also be helpful, as significant liver involvement is less likely to occur with a *PKD1* or −2 mutation. A genetic panel for cystic kidney diseases may be necessary in some cases to help differentiate these conditions (or combined mutations) and is of particular value for severe early presentation.

HNF1β-nephropathy is an autosomal dominant condition with widely varying phenotype which may include uni- or bilateral cysts, enlarged kidneys, hypodysplasia, or agenesis. Many patients are described with abnormal prenatal ultrasound with enlarged kidneys with increased echogenicity [34], similar to ADPKD or ARPKD, but there may be associated anomalies such as genital or pancreatic malformations. A family history of kidney or pancreatic disease, hyperuricemia, hypomagnesemia, or maturity onset diabetes of the young type 5 should raise particular concern for this diagnosis. Of note, however, 50% of cases carry de novo mutations with a negative family history. Genetic testing is needed to confirm diagnosis.

Simple kidney cysts are rarely seen in children but increase in frequency with age, with an incidence of less than 0.5% in children reported in 1991 [87] but more than 10% in adults aged 50 years and older [29]. With advanced imaging techniques and widespread application of various radiographic modalities in childhood, experience suggests that the incidence of simple cysts in childhood is higher than previously reported. By definition a simple cyst occurs in the kidney with otherwise normal parenchyma and a normal contralateral kidney. Simple cysts appear as round, thin-walled, anechoic, non-septated cysts, separate from the collecting system, with no Doppler blood flow [55]. Because single kidney cysts are rare in children and may be the first manifestation of an underlying pathologic cystic kidney disease, it is important to perform a detailed medical and family history and to pursue appropriate follow-up ultrasound examination to ensure no development of additional cysts or change in cyst size or imaging characteristics.

Tuberous sclerosis complex (TSC) is usually diagnosed based on clinical and other imaging features before significant kidney involvement is evident. Angiomyolipomata are the most common kidney manifestation of classic TSC and are also a major clinical diagnostic feature. Kidney cysts affect about 40% of children with classic TSC; the presence of multiple kidney cysts is considered a minor clinical diagnostic feature [72]. In classic TSC, kidney cysts are usually small and few in number. However, patients with the TSC2/PKD1 contiguous gene syndrome demonstrate a kidney phenotype associated with severe large bilateral cysts evident from early in life with associated severe kidney enlargement and high risk of progression to early ESRD [80].

Multicystic dysplastic kidney (MCDK) is characterized by replacement of the entire kidney with multiple disorganized cysts of varying size lacking any normal surrounding parenchyma. Such “kidneys” have no function. Thus, bilateral MCDK is associated with development of anhydramnios and anticipated perinatal death due to Potter sequence. In childhood, ADPKD does rarely present with asymmetric disease, but the severity of the unilateral MCDK’s architectural distortion and the lack of function by nuclear scan should help to differentiate these conditions. Renal cystic dysplasia is characterized by the finding of at least one cyst within an abnormal-appearing kidney, for example, hyperechogenicity, small kidney, loss of corticomedullary differentiation. The extent of structural kidney disease can be variable and can affect one or both kidneys. Such cystic dysplastic kidneys do not tend to be enlarged but rather normal to small in size and with more impressive parenchymal abnormality than typically observed between the cysts of ADPKD. Dilated calyces in patients with high-grade obstruction or urinoma can also be misdiagnosed as renal cysts. If concern exists, diuretic renal scan and urologic consultation are helpful [55].

Nephronophthisis is typically associated with normal-sized to small kidneys and bilateral increased echogenicity. Corticomedullary cysts can occur in nephronophthisis but in most cases are not evident until late in the course of the disease. The condition can manifest as isolated kidney disease or as part of a syndrome with associated manifestations in other organs. Extrarenal manifestations or deteriorating kidney function in the absence of extensive structural cystic kidney disease can help to differentiate nephronophthisis from ADPKD.

Cystic tumors are fortunately rare in childhood. Concerning signs of malignancy by ultrasound include a unilateral single cystic mass with a thickened wall, septations, and possibly calcifications, with enhanced perfusion on color Doppler imaging [55]. Numerous cystic lesions would be uncommon with kidney malignancy. More extensive imaging by CT or MRI to examine the lesion as well as assess abdominal lymph nodes and potential tumor infiltration into surrounding tissues or venous system is needed if malignancy is suspected.

Prognosis

Given the growing recognition that clinical manifestations and progressive structural kidney disease are occurring in children with ADPKD, it is critical to have a means to identify patients who are at the highest risk of disease progression in order to optimize individual treatment and to encourage appropriate participation in research trials. In this regard, studies have identified several factors which are associated with poor prognosis in adults with ADPKD. These include: onset of hypertension before 35 years of age; first episode of gross hematuria before 30 years of age [31]; hyperlipidemia and increased body mass index [99]; high urine sodium excretion [144]; decreased kidney blood flow [139]; large total kidney volume [24, 70]; and presence of a truncating PKD1 mutation [30, 66].

Such observations have led to the development and validation of prognostic tools to identify older adolescents and adult patients at highest risk for progression to ESKD. Irazabal et al. [70] formulated a risk prediction tool based on radiographic imaging from MRI/CT data from 590 ADPKD patents aged 15–80 years, with serum creatinine under 5 mg/dL within 6 months of imaging, and with at least two follow-up measurements of serum creatinine before reaching ESKD. The tool initially excludes atypical cases with marked asymmetry which are not suitable for the model and then stratifies the typical cases into five classes (A-E) based on growth rates (<1.5%, 1.5–3%, 3–4.5%, 4.5–6%, or >6% per year) estimated from patient age and theoretical starting htTKV of 150 mL/m. The model has been validated in other adult ADPKD cohorts and can be utilized to predict future GFR decline with reasonable accuracy. Patients in class 1C-1E are considered most likely to benefit from more aggressive or novel interventions. This imaging calculator can be used from the age of 15 years.

The Predicting Renal Outcome in Polycystic Kidney Disease (PROPKD) score was developed from 1341 ADPKD patients with a median age of 54.7 years and focuses on clinical and genetic parameters to stratify risk of kidney disease progression [31]. This score is typically applied from 35 years of age or older and assesses the presence of high-risk variables linked to age at ESKD onset including male gender [1 point], hypertension before 35 years of age [2 points], first urologic event before 35 years of age [gross hematuria, symptomatic cyst hemorrhage, cyst infections, flank pain due to cysts; 2 points], and genetic mutation (*PKD2* [0 points] versus non-truncating *PKD1* [2 points] versus truncating *PKD1* mutation [4 points]). With a scoring system from 0 to 9, the risk categories include low risk (0–3 points), intermediate risk (4–6 points), and high risk (7–9 points) of progression to ESKD, with corresponding observed median ages for ESKD onset of 70.6, 56.9, and 49 years, respectively. A score of 3 or below eliminated evolution to ESKD before 60 years of age with a negative predictive value of 81%, while a score greater than 6 predicted ESKD onset before 60 years of age with a positive predictive value of 90%. A modified version is available when genetic mutation is not known.

As yet no studies have delineated the factors occurring early in life which identify high-risk children with ADPKD, although research in this area is ongoing. Large registries may prove helpful in this regard. Recently, a new initiative has been launched to provide an observational evidence base for unified diagnostic, follow-up, and treatment approaches for ADPKD children. The ADPedKD registry is a World Wide Web-based database, including both retrospective and prospective longitudinal data from young ADPKD patients [35].

Treatment

Lifestyle measures. In recent years, much attention has focused on lifestyle measures which patients can implement to optimize health in

ADPKD. Given data suggesting a potential deleterious role of arginine vasopressin (AVP) in kidney cyst development, there has been interest in whether high water intake alone could suppress endogenous AVP concentration and thereby reduce kidney cyst growth [140]. The ease of access, minimal side effects, and minimal expense make this a highly desirable intervention if effective. Studies in adults have shown that water intake to target a goal urine osmolality below 280 mOsm/kg H_2O is attainable [148] and that the required daily water intake to achieve the urinary dilution goal can be reduced with a low-solute diet [2]. Longer randomized controlled trials to examine the impact of high water intake on TKV are in progress in ADPKD adults [153]. High fluid intake might also be generally beneficial to reduce the risk of nephrolithiasis and UTI in ADPKD. The CRISP study of polycystic kidney disease and a post-hoc analysis of the HALT-PKD clinical trials of renin-angiotensin blockade, both primarily consisting of adult ADPKD participants, suggested that higher dietary sodium intake was associated with faster growth of kidney cysts [141, 144]. Given this concern and the high risk of hypertension in pediatric ADPKD as compared to the general population, education for children and families on appropriate dietary sodium intake is worthwhile. With the rising prevalence of childhood obesity and its associated cardiovascular risk factors, targeting normal body mass index (BMI) is recommended for general health in children. Studies in adult ADPKD have also reported that BMI ≥ 30 kg/m^2 is associated with faster increase in TKV and decline in eGFR over time [99]. More recently interest has arisen in metabolic dysfunction underlying epithelial cell proliferation in ADPKD and whether dietary interventions such as daily caloric restriction, intermittent fasting, time-restricted feeding, or a ketogenic diet could be beneficial for metabolic reprogramming (reviewed in [101]). The relevance to and safety in affected children would require further study. As cardiovascular disease is the most frequent cause of mortality in ADPKD, routine monitoring and appropriate intervention for hyperlipidemia and avoidance of smoking/vaping are reasonable recommendations. Avoidance of potential nephrotoxins whenever possible including nonsteroidal anti-inflammatory drugs is also appropriate.

Blood pressure control. Controlling hypertension is a critical aspect of chronic kidney disease management in both children and adults. Lifestyle counseling with respect to appropriate dietary sodium restriction, routine activity, and targeting normal body mass index is indicated as the initial measure and is an important component of anticipatory guidance for at-risk individuals and those diagnosed with ADPKD, both with and without hypertension. When pharmacologic treatment is necessary, blockade of RAAS is usually the preferred mechanism due to concern for RAAS activation as a major contributor to ADPKD-related hypertension and effect to decrease chronic proteinuria and glomerular hyperfiltration.

Although multiple studies have suggested a role for aggressive control of hypertension to delay deterioration in kidney function in adults and children with chronic kidney disease [40, 74], the optimal level of blood pressure control in pediatric ADPKD is not well established. A five-year interventional trial in ADPKD children and young adults ages 4–21 years was conducted to examine the effect of aggressive blood pressure control with ACEI in participants with hypertension (blood pressure above the 95th percentile for height, sex, and age; randomized to ACEI treatment with enalapril with goal blood pressure at the 90th versus 50th percentile) and participants with high normal blood pressure (75th to 95th percentile for height, sex, and age; randomized to either enalapril with goal blood pressure at the 50th percentile or to observation without treatment unless hypertension developed) [15]. Regardless of the degree of hypertension control, participants in both hypertensive groups had a significant increase in TKV and decrease in eGFR over the study period. No significant differences were observed in LVMI or urine albumin excretion between study groups or over time. These results emphasized the high risk for structural and functional kidney disease progression associated with established hypertension, even in ADPKD children. With high normal blood pressure, both study groups also demonstrated significant increase in TKV over time. However, participants randomized to observation showed a decline in eGFR and increase in LVMI over time while these parameters were stable in the ACEI-treated group. These findings suggested that children and young adults with ADPKD and high normal blood pressure may represent a subgroup for whom rigorous control of blood pressure with ACEI could provide kidney functional and cardiovascular benefit. Important limitations of the clinical trial included a relatively small number of participants as compared to adult trials despite recruitment across the United States, suboptimal achievement of blood pressure goals in the aggressively treated hypertensive group, and a generous dropout rate (27% overall).

Subsequently, the multicenter HALT-PKD trial was conducted [124]. This double-blind, placebo-controlled trial included 558 hypertensive participants 15–49 years of age, with early stage ADPKD (eGFR >60 mL/min/1.73 m^2) who were randomized to either a standard blood pressure target (120/70–130/80 mmHg) or to a low blood pressure target (95/60–110/75 mmHg) and to either the ACEI lisinopril plus the angiotensin receptor blocker telmisartan or to lisinopril plus placebo. Serial follow-up was performed for 5–8 years with a primary outcome of annual percentage change in TKV by MRI. The trial included a very limited number of pediatric participants, with mean age of study participants overall of 36 ± 8 years. Combined lisinopril/telmisartan did not significantly impact the rate of increase in TKV as compared to lisinopril/placebo. However, as compared to standard blood pressure control, the rigorous blood pressure control group demonstrated a small (1.1% per year) but statistically significant reduction in TKV and no change in eGFR. Of note, there was no control arm without RAAS, limiting the ability of this trial to assess the specific effect of RAAS blockade on TKV. Limitations of the study included a higher frequency of PKD2 mutations in the low BP group and a limited number of participants reaching blood pressure goals on a consistent basis. Based on the trial, aggressive control of blood pressure was recommended for this group of patients.

The KDIGO Controversy Conference on ADPKD [25] advised a target blood pressure of less than 140/90 in adults with ADPKD with a stricter goal below 130/80 if macroalbuminuria was present. They further recommended management of hypertension in ADPKD children per routine guidelines for the general pediatric population (goal below the 90th percentile for age, sex and height) and supported RAAS blockade as the preferred first-line treatment for hypertension in ADPKD. More recently, international consensus guidelines specific to pediatric ADPKD [56] recommended at least annual blood pressure measurement for children at-risk of or diagnosed with ADPKD with a preference for periodic 24-hour ambulatory blood pressure monitoring due to the increased risk of masked hypertension and advised blood pressure goal below the 75th percentile or $< 125/72$ mmHg for age greater than 16 years. Further, they noted that lowering blood pressure below the 50th percentile or $< 120/70$ mmHg if over 16 years of age might provide additional long-term benefit for hypertensive children with ADPKD, although with limited firm evidence to support this conclusion. Thus it seems reasonable to target 50th–75th percentile blood pressure goals for hypertensive children with ADPKD.

Pharmacologic therapy for ADPKD. With advances in the understanding of the mechanisms which contribute to kidney cyst development, the last two decades have seen a major increase in interventional clinical trials, particularly in early stage ADPKD, designed to mitigate progressive development of kidney cysts and thereby slow progression to ESKD (Fig. 1).

mTOR inhibitors. Inhibitors of the mechanistic target of rapamycin (mTOR) have been utilized in clinical trials of adult ADPKD with disappointing results. The mTOR pathway has an important role in cell growth and proliferation, including interactions of the cytoplasmic tail of polycystin-1 with tuberin. Animal studies suggested that rapamycin, an inhibitor of mTOR, reduced cystogenesis in a dose-dependent fashion [157]. Unfortunately, however, sirolimus treatment had no impact on TKV or kidney function in an 18-month clinical trial in adults with ADPKD with normal kidney function [126]. Gastrointestinal side effects were common, with 82% of treated participants complaining of mucositis. Similarly, everolimus treatment for

2 years in adults with ADPKD resulted in a nonsignificant slower rate of increase in TKV and faster decline in eGFR [147]. Mucositis and cytopenias were common in the treatment group. For both studies, concern was raised that appropriate local (i.e., kidney cyst) concentrations of drug were not achieved before systemic side effects prevailed. These medications have not been studied in pediatric ADPKD but other than TSC2/PKD1 contiguous gene syndrome, use is likely to be limited by the high rate of side effects and concern for potential adverse effects of long-term immunosuppression.

Somatostatin analogs. Somatostatin analogs including octreotide and lanreotide have been attempted in adults with ADPKD to manage both polycystic kidney and polycystic liver disease. Such medications inhibit cAMP production via stimulation of Gαi. The ALADIN trial reported decreased rate of growth in TKV after 1 year of treatment with octreotide, but the effect was not sustained at 3 years of study [18, 111]. An observational study of 6 months' treatment with lanreotide in adults with polycystic liver and kidney disease demonstrated a statistically significant but clinically minimal decrease in median TKV (1023 to 1012 mL; $p = 0.0006$) [54]. These medications may have a more valuable role in management of PKD-associated polycystic liver disease, which is not a feature of childhood ADPKD.

Statin therapy. HMG–CoA reductase inhibitors (statins) improve kidney blood flow and eGFR and attenuate inflammation through vascular and glomerular nitric oxide production [86]. Lovastatin treatment reduced the severity of functional and structural kidney disease in an animal model of ADPKD [158] with subsequent studies attributing these effects to statin-mediated reduction in arachidonic acid-mediated inflammatory markers, normalization of metabolism of nitric oxide precursors, and improvement in kidney energy cell metabolism [76]. In a prospective, double-blind, randomized controlled clinical trial of 110 children and young adults aged 8–22 years with ADPKD and normal kidney function, treatment with pravastatin resulted in a significantly slower increase in htTKV over time as compared to placebo (23 ± 3 vs. 31 ± 3% per 3 years; $P = 0.02$) [17]. All participants were treated with lisinopril with target blood pressure at the 50th to 75th percentile. As anticipated, eGFR did not differ between the groups. LDL and total cholesterol levels were not directly correlated with clinical outcome variables including htTKV, albuminuria, or LVMI. Pravastatin therapy was associated with reduction in plasma concentrations of cyclooxygenase- and lipoxygenase-derived plasma lipid mediators known to enhance the pro-fibrotic effects of angiotensin II and to activate the peroxisome proliferator–activated receptor ɣ (PPARɣ) which has been implicated in cyst growth [77]. The medication was well-tolerated in the cohort. Subsequently, a secondary analysis of the HALT-PKD clinical trial described no effect of self-reported statin use versus no statin use on TKV in adults with ADPKD [12]. It is important to note that statin use was not randomized or controlled in the HALT-PKD trial and that the study participants also had significantly more advanced disease than the pediatric population described above. Whether an antiproliferative effect of statins is more impactful early in the course of ADPKD, as has been observed with statins and renal hemodynamics [159], remains to be seen. In this regard, a controlled clinical trial in adults with early-stage ADPKD is ongoing (NCT03273413).

Vasopressin V_2 receptor blockade. In 1989, Grantham et al. reported that in contrast to normal human kidney cells, ADPKD cells demonstrated vasopressin-induced cAMP-stimulated chloride-driven fluid secretion, bringing focus to cAMP as a critical regulator of kidney cyst growth in ADPKD and potential therapeutic target [59, 89]. Several years later, pharmacologic vasopressin V_2 receptor antagonists became available. Treatment with such agents was associated with a marked decrease in cyst fluid accumulation in several rat and mouse models of polycystic kidney disease [52, 138, 150]. These studies formed the basis of the multicenter international TEMPO 3:4 clinical trial which included nearly 1500 adults aged 18–50 years with ADPKD, eGFR >60 mL/min per 1.73 m^2, and large kidneys (TKV ≥750 mL) who were randomized to vasopressin V_2 receptor blockade with tolvaptan or to placebo for 3 years

[142]. Participants receiving tolvaptan demonstrated slower annual increase in TKV (2.8 vs. 5.5%; $P < 0.001$) and slower annual decline in kidney function (-2.6 vs. -3.8 mg/mL; $P < 0.001$) than controls. Suppression of plasma AVP was observed in both groups and was attributed to voluntary water intake by placebo participants. It is important to note that these trial participants had relatively advanced structural kidney disease and thus the magnitude of benefit to the general and more specifically to the pediatric ADPKD population requires further study. Subsequently, tolvaptan was approved for rapidly progressive ADPKD in adults in several countries around the world. There is some variability in the definition of "rapidly progressive," and several panels have published statements in this regard [27, 50, 67]. Of note, there is concern for potential hepatotoxicity with tolvaptan which can be severe and irreversible in some cases.

The therapeutic potential of tolvaptan in patients at risk of early disease progression might be even greater at pediatric age, when the kidney has not yet been irreversibly damaged by cyst growth [122]. A phase 3 study evaluating tolvaptan over 3 years in children and adolescents with ADPKD is ongoing. This trial aims to evaluate the pharmacodynamic properties, safety, and efficacy of tolvaptan in this young population. In addition, lixivaptan, a nonpeptide V_2R antagonist with potentially less hepatotoxicity [155], will be evaluated in a phase 3 adult trial that will start recruiting patients in 2021.

Curcumin. Curcumin is found in the spice turmeric and is a naturally occurring polyphenol which has the ability to activate transcription of antioxidants, suppress inflammation, and reduce cell proliferation, leading to its application in several conditions of abnormal cell growth. It has been shown to mitigate acute and chronic kidney injury, possibly by diminishing activation of the pro-inflammatory transcription factor NFkB and its downstream target tumor necrosis factor-α (TNF-α) as well as enhancing the anti-inflammatory transcription factor PPARɣ [84]. Through effects on intracellular signaling proteins, curcumin has been shown to reduce kidney cyst growth in vitro in a dose-response manner [51]. In the Pkd–1 deletion mouse model, curcumin treatment improved kidney histology and cystic proliferation [82]. Curcumin also has effects on vascular function which have been attributed to increased vascular nitric oxide bioavailability and arterial eNOS expression and reduced vascular oxidative stress [44, 95]. As noted previously, vascular dysfunction is a common derangement associated with ADPKD in both children and adults and is thought to increase long-term risk of cardiovascular disease. Upon this background, a randomized placebo-controlled interventional trial of curcumin therapy was conducted in children and young adults with ADPKD [100]. The study assessed brachial artery flow-mediated dilation and aortic pulse wave velocity at baseline and following 12 months of curcumin treatment versus placebo. Secondary outcome measures included htTKV as well as urine and plasma markers of inflammation and oxidative stress. Results are anticipated in late 2021.

AMPK activation. An alternate approach to suppress mTOR activity is via stimulation of AMP-activated kinase (AMPK) [92]. In this regard, metformin, which is a pharmacological activator of AMPK, has been demonstrated to arrest cyst growth in mouse models of PKD [132]. The medication is relatively inexpensive, has widespread use in diabetes mellitus and polycystic ovary syndrome in both adults and children, and may have some anti-inflammatory and anti-fibrotic effects which could be of potential benefit for vascular dysfunction in ADPKD. Clinical trials are ongoing in adult ADPKD.

Tyrosine kinase inhibitors. Epidermal growth factor (EGF) receptor is known to be overexpressed and mislocalized to the apical membrane in both ADPKD and ARPKD [38, 116]. Tyrosine kinase inhibitors that block EGF receptor activity and its downstream signaling have been shown to slow disease progression in rodent models of PKD [130]. A phase 2, randomized placebo-controlled multicenter study of the oral dual Src/Bcr-Abl tyrosine kinase inhibitor bosutinib was undertaken in adults with ADPKD with relatively preserved eGFR and large kidneys (TKV $\geq$ 750 ml) [135]. Bosutinib was associated with a reduction in annual rate of kidney enlargement (0.84% vs. 4.74%) as compared with controls, with similar annualized eGFR decline. However, there was a high rate of bosutinib-related gastrointestinal and liver adverse events including the need for permanent discontinuation of bosutinib in several participants. Such findings raise concern for the generalized effect of tyrosine kinase inhibitors on proliferating cells when more targeted impact on kidney cyst epithelium is desired. Safety and tolerability may thus limit the application of these medications in the near future to pediatric ADPKD.

Others. Venglustat is an inhibitor of the enzyme glycosylceramide synthase (GCS) which catalyzes an early step in the synthesis of many glycolipids. GCS inhibition has been shown to reduce cystogenesis, improve urinary concentration, and reduce the rate of renal functional decline in three animal models of polycystic kidney disease including the orthologous ADPKD mouse [96], suggesting a potential role for compounds like venglustat in patients with ADPKD. A phase 1 trial in healthy volunteers suggested a favorable safety and tolerability profile for venglustat [108], and a multicenter, randomized, double-blind, placebo-controlled study to examine the efficacy and safety of venglustat on TKV growth and eGFR decline in adult patients at risk for rapidly progressive ADPKD is now in progress (STAGED-PKD; NCT03523728). Bardoxolone exerts antioxidant activity by promoting the activation of nuclear factor erythroid2 derivative (Nrf2) and downregulation of the proinflammatory NF-kB. In renal cortical collecting duct cells, tolvaptan has been shown to activate the Nrf2 antioxidant pathway through a different mechanism than bardoxolone, suggesting potential for synergistic effects [45]. A multicenter, randomized, double-blind, placebo-controlled phase 3 clinical trial evaluating the safety, tolerability, and effect of bardoxolone on eGFR decline in adults with ADPKD is underway (FALCON; NCT03918447).

Conclusion

The recent progress in understanding the pathophysiology and disease progression in ADPKD led to the approval of tolvaptan as the only disease-specific medication for ADPKD. However, with its limited therapeutic achievements and severe side effects, there is still an unmet need to identify efficacious drugs. Because deterioration of renal function is not observed until the destruction of at least 50% of the parenchyma, therapies implemented at later stages are less likely to be successful since the patient may already have reached a point of no return. Consequently, research to identify new biological targets and surrogates for disease progression are strongly required as children and young adults with ADPKD may represent the critical therapeutic window to reduce future renal and cardiovascular risk. Walking in this road of progress, the ultimate goal of the pediatric community should be to empower patients and families to make their own informed decisions, to advise follow-up and treatment of ADPKD children with early manifestations, and to monitor at-risk children for disease manifestations such as hypertension and proteinuria. Treatment of these disease-modifying factors and improving the lifestyle early in ADPKD might impact the long-term outcome. The World Wide Web-based ADPedKD registry initiative demonstrated the strong collaborative commitment of the pediatric community to improve this gap by raising awareness of this disease and will help to generate further observational evidence for clinical and therapeutic recommendations.

Abstract

Autosomal recessive polycystic kidney disease (ARPKD) is a monogenic disorder that primarily involves mutations in the *PKHD1* gene, although rare, atypical forms of ARPKD due to mutations in other genes have recently been described. For years, pediatric nephrologists have directed the clinical management of these patients. However, there is increasing recognition that ARPKD has multisystem effects and a comprehensive care strategy requires a multidisciplinary team. In severely

affected infants, the diagnosis is often first suspected by obstetricians based on detection of enlarged, echogenic kidneys and oligohydramnios on prenatal ultrasounds. Neonatologists are central to the care of these infants, who may have respiratory compromise due to pulmonary hypoplasia and massively enlarged kidneys. Variability in the clinical expression of ARPKD liver disease requires pediatric hepatology evaluation and management. Surgical considerations range from the advisability of nephrectomy to relieve mass effects, placement of dialysis access, and kidney and/or liver transplantation. Families of patients with ARPKD also face decisions regarding genetic testing of affected children, testing of asymptomatic siblings, or consideration of preimplantation genetic diagnosis for future pregnancies. These considerations require the expertise of genetic counselors, geneticists, and reproductive endocrinologists. This chapter will discuss the clinical and genetic diagnosis ARPKD, current insights into the genetics and pathobiology of this disorder, management of organ-specific complications, and close with considering future directions for prognostic prediction of disease outcomes and the development of targeted therapies.

ARPKD · ADPKD · *PKHD1* · FPC · Hepatorenal fibrocystic diseases

Introduction

Polycystic kidney diseases (PKD) are among the most frequent genetic causes of chronic kidney failure in children and adults. Autosomal dominant polycystic kidney disease (ADPKD) and autosomal recessive polycystic kidney disease (ARPKD) are cilia-related disorders characterized by fibrocystic hepatorenal changes and variable systemic manifestations [1]. Emerging evidence suggests while these disorders are phenotypically distinct, there is mechanistic overlap in their pathobiology. This chapter focuses on ARPKD, the rarer and often more severe form of PKD that typically presents antenatally or in early childhood [2, 3]. With its attendant significant morbidity and mortality, ARPKD is widely considered to be one of the most challenging disorders to manage, even in in the most advanced pediatric centers [4, 5].

Epidemiology, Diagnosis, and Pathology

ARPKD is a rare disease with an estimated incidence of 1 in 20,000 live births and carrier frequency of 1:70 [1, 4, 6]. Variability in the reported incidence is likely a consequence of multiple factors including higher disease frequency in isolated populations [7, 8], variation in inclusion criteria, and the confounding impact of genetically distinct diseases that can phenocopy the clinical presentation of ARPKD [9]. A recent study in the USA based on electronic health record (EHR) data calculated an annualized incidence of 1:26,485 live births [10].

ARPKD is mainly caused by variants in the gene *polycystic kidney and hepatic disease 1* (*PKHD1*) on chromosome 6 [11, 12]. In addition, variants in the gene *DAZ interacting zinc finger protein 1 like* (*DZIP1L*) on chromosome 3 have been identified in a few patients with an ARPKD phenotype [13]. Details on the genetics are discussed later in this chapter.

The clinical diagnosis of ARPKD is suspected according to the modified Zerres criteria: typical kidney imaging findings in addition to one or more of the following: (1) typical liver imaging, clinical or laboratory findings consistent with congenital hepatic fibrosis, (2) liver pathology showing biliary ductal plate malformation, (3) negative standard ultrasound findings in both parents or characteristic findings on high-resolution ultrasonography, and (4) diagnosis of ARPKD in an affected sibling by either pathology or genetics [14, 15]. In highly resourced countries, antenatal suspicion of ARPKD is raised by detection of enlarged, diffusely echogenic kidneys on routine antenatal screening [5, 16].

After birth, sonography typically reveals bilaterally enlarged, reniform kidneys with poor corticomedullary differentiation due to the ubiquitous microcysts that typically start in the medulla and radiate into the cortex [5, 17–19]. Typical images of kidney and liver disease are presented in Fig. 1. ARPKD has long been described as having a “salt and pepper” pattern on renal sonography. However, this pattern is now commonly observed among a range of ciliopathy-related renal cystic diseases [20]. On high-resolution ultrasound, diffuse corticomedullary involvement was associated with poorer renal outcome as compared to predominant medullary involvement [19]. Bilateral pelvicaliectasis and calcifications in the kidney have also been reported in ARPKD patients [6, 21].

Macrocysts may develop during the course of the childhood and thus, distinguishing ARPKD and other cystic kidney disorders such as HNF1B-nephropathy or early onset ADPKD may be difficult [17, 19]. Unlike in ADPKD, kidney length in ARPKD does not inexorably increase and renal growth may slow or kidney size contract as children age [22]. While total kidney volume (TKV) is a well-established prognostic marker in ADPKD [23], its prognostic value in ARPKD is less clear. There is no clear correlation between kidney length and renal function or length of the disease course [18]. However, one study reported a limited inverse correlation between body-surface-adjusted total kidney volume and renal function in an ARPKD cohort [24].

Different histopathological patterns have been described that may depend on the patient age and the extent of renal cystic disease. Typically, fusiform dilatations of the tubules and collecting ducts show radial expansion from the medulla to the cortex [25] (Fig. 2a–c). These dilatations are lined with columnar or cuboidal epithelium and remain in continuity with the full nephron [1]. A transient phase of proximal tubular cyst formation has been described in the fetal kidney as well as various mouse PKD models, but proximal tubular cysts are absent at birth in human ARPKD [25–27]. Dysplastic elements are not observed in ARPKD kidneys.

In addition to the cystic transformation of the epithelia-lined tubules, there is progressive interstitial fibrosis in ARPKD kidneys. A study of 54 fetuses following medical termination of pregnancy and 20 neonates who died perinatally found that the severity of cortical collecting duct dilatations, cortical tubular and glomerular lesions, and renal cortical and hepatic portal fibrosis increased with gestational age [25]. Moreover, the severity of cortical tubular lesions, glomerular lesions, and cortical fibrosis significantly correlated with the extent of collecting duct dilatation. Dilatations of the proximal tubule were observed almost exclusively prior to 30 weeks gestational age.

The ARPKD liver lesion is characterized by hepatobiliary changes that arise from the “ductal plate malformation,” in which defective remodeling of the developing biliary tree and the associated portal vein ramifications results in congenital hepatic fibrosis (CHF) [28, 29]. Biliary ectasia and dilatations can affect both intra- and

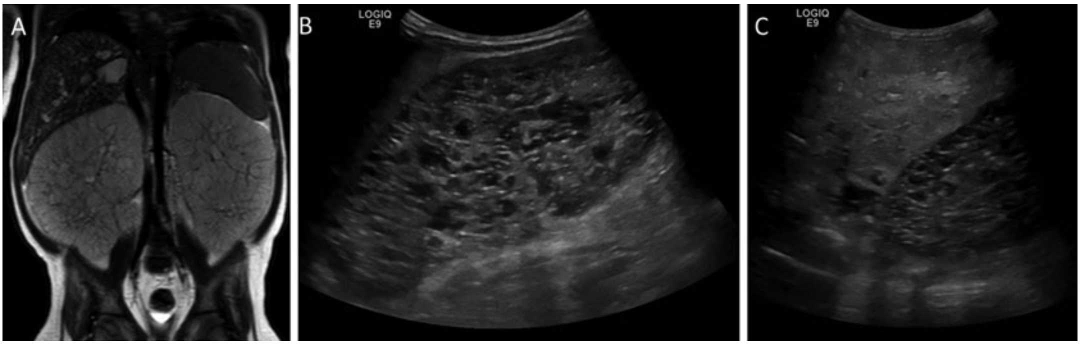

Fig. 1 Radiological features of ARPKD. Typical radiological features of ARPKD kidney and liver disease with massively enlarged and cystic kidneys as detected by coronal MRI (**a**) or ultrasound (**b**). Also note the dilated bile ducts in the MRI. Ultrasound shows inhomogeneous liver parenchyma during the course of the disease (**c**)

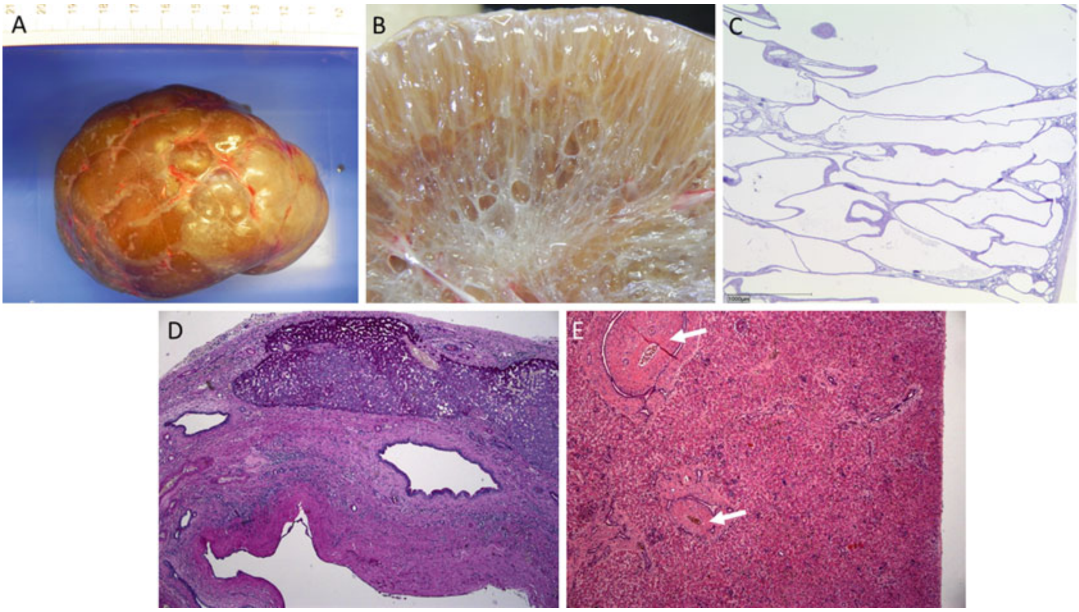

Fig. 2 Histopathological features of ARPKD. Macroscopic appearance of enlarged reniform kidneys (**a**) with ubiquitous tubular microcysts (**b**, **c**). Liver histology shows dilated bile ducts in an example of Caroli's syndrome (**d**) and the typical appearance of ductal plate malformation (**e**)

extrahepatic bile ducts. The most severe expression, involving both dilated bile ducts and congenital hepatic fibrosis, is termed Caroli's syndrome (Fig. 2d–e). ARPKD liver disease is characterized by progressive portal fibrosis, often with the development of fibrous septae that isolate normal liver parenchyma with functioning hepatocytes. Clinically, these histopathological features can result in portal hypertension and increased risk for cholangitis, while hepatocellular function (and thus serum transaminase levels) remains within the normal range [29–32].

Genetics

Molecular Basis of Disease

All typical forms of ARPKD are caused by mutations in *PKHD1*, which is among the largest human disease genes extending over 470 kb in the genomic sequence. Of the predicted 86 exons in *PKHD1*, 67 comprise the longest open reading frame which encodes fibrocystin/polyductin (FPC), a 4074 amino acid protein [12]. The gene appears to be transcriptionally complex, perhaps more so in the mouse than in humans [12, 33]. More than 700 pathogenic *PKHD1* mutations have been catalogued in the ARPKD mutation database (http://www.humgen.rwth-aachen.de) [34]. These variants have been identified along the entire length of the gene and approximately half are missense changes. While there is no apparent mutational hot spot, a missense mutation in exon 3, c.107C>T (p.Thr36Met), has been observed in a number of unrelated patients and accounts for approximately 15–20% of all mutant alleles [35].

Genotype-Phenotype Correlations

Multiple studies have examined ARPKD cohorts for potential genotype-phenotype correlations. Most patients are compound heterozygotes for *PKHD1* mutations and the functional effect of any particular mutant allele can be difficult to discern. Nevertheless, some broad themes are emerging. Notably, patients with two truncating mutations typically have a severe phenotype leading to perinatal or neonatal mortality, whereas missense mutations are typically associated with neonatal survival [9, 16, 35, 36]. No substantial clinical differences have been reported between patients with two missense mutations and patients with missense and truncating mutations *in trans*, suggesting that the missense mutation defines the disease severity (reviewed in [9]). In a recent study, the European ARegPKD Consortium found that the position of *PKHD1* variants is important in determining the phenotype. Patients with two missense variants affecting FPC amino acids 709–1837 or a missense variant in this region combined with a null variant less frequently develop end-stage kidney disease (ESKD). Patients with missense variants affecting FPC amino acids 1838–2624 have less severe liver disease, whereas variants affecting amino acids 2625–4074 are associated with poorer hepatic outcome [37].

However, there are notable exceptions. For example, children homozygous for *PKHD1* deletions or truncating mutations have survived well past the neonatal period [38, 39]. Moreover, not all missense mutations lead to a relatively less severe outcome, suggesting that missense variants have diverse impact on protein function [35]. Genetic and perhaps environmental modifiers likely also play a significant role in disease expression, as illustrated by significant phenotypic variability in subsets of families [40]. Taken together, these genetic features pose particular challenges for genetic counseling of ARPKD families.

Atypical ARPKD and Phenocopy Disorders

ARPKD is generally considered a genetically homogeneous disease. However, a recent report described seven children from four unrelated, consanguineous families with an atypical form of ARPKD that results from mutations in a second gene, *DZIP1L* [13]. The children presented with hypertension and large, cystic kidneys; some progressed to ESKD. A distinguishing feature of this ARPKD phenotype is the more moderate renal disease and the absence of clinically apparent liver disease.

The *DZIP1L* gene spans about 53 kb and encodes a 767 amino acid ciliary transition zone protein, DAZ interacting zinc finger protein 1 like (DZIP1L). Among the four reported families, two families had different homozygous missense changes predicted to be pathogenic, while the other two had distinct, homozygous truncating mutations. While the function of DZIP1L is largely unknown, it is implicated in hedgehog signaling and ciliogenesis.

The *cpk* mouse carrying a spontaneous truncating mutation in *Cys1* has been the most widely studied mouse model of ARPKD [41]. However, the relevance of this mouse model for human disease has been unclear. A recent report describes the first case of human ARPKD due to homozygosity for a *CYS1* variant, c.818+5G>A, which is predicted to disrupt splicing [42]. While it is surprising that *CYS1* deficiency causing ARPKD has been observed in only one family, this small gene has an extensive GC-rich region in its first exon. Such GC-rich regions can be difficult to amplify and sequence using Sanger sequencing and even next-generation sequencing [43].

ARPKD is the prototype of the hepatorenal fibrocystic diseases (HRFD; Table 1), a subset of recessively transmitted cilia-related disorders (ciliopathies) that are characterized by renal cystic disease and can be associated with congenital hepatic fibrosis and/or Caroli syndrome, as well as extrarenal manifestations [44]. These rarer disorders in which the kidney disease can phenocopy ARPKD include: nephronophthisis (MIM 256100), Joubert syndrome (MIM 213300), Bardet-Biedl syndrome (MIM 209900), Meckel-Gruber syndrome (MIM 249000), and oro-facial-digital syndrome I (MIM 311200). As with FPC and DZIP1L, the proteins disrupted in these disorders are critical in the structure/function of the primary apical cilium [41].

Finally, a form of PKD that can mimic either ARPKD or ADPKD and is associated with hyperinsulinemic hypoglycemia (HIPKD) has been described in 11 pedigrees, who had biallelic mutations in *PMM2,* which encodes phosphomannomutase 2 [45]. PMM2 is a key enzyme in N-linked glycosylation, and recessive mutations in *PMM2* are usually associated with congenital

Table 1 ARPKD and other hepatorenal fibrocystic diseases

Disease	Gene(s)	Renal disease	Hepatic disease	Associated features
ARPKD	*PKHD1; DZIP1L: CYS1*	Collecting duct dilatation	CHF[a]; Caroli syndrome	Growth retardation
ADPKD	*PKD1; PKD2; GANAB*	Cysts along entire nephron	Biliary cysts; CHF	Minimal in children
Nephronophthisis (NPHP)	*NPHP1-NPHP20*	Cysts at the corticomedullary junction	CHF	Tapetoretinal degeneration; situs inversus
Joubert syndrome (JBTS)	*JBTS1-JBTS37*	Cystic dysplasia; NPHP	CHF; Caroli syndrome	Cerebellar vermis hypo/aplasia with episodic hyperpnea; abnormal eye movements; intellectual disability
Bardet-Biedl syndrome (BBS)	*BBS1-BBS21*	Cystic dysplasia; NPHP	CHF	Retinal degeneration; obesity; post-axial polydactyly; hypogonadism in males; intellectual disability
Meckel syndrome (MKS)	*MKS1-MKS13*	Cystic dysplasia	CHF	Occipital encephalocele; polydactyly
Oral-facial-digital syndrome, type I (OFD1)	*CXORF5*	Glomerular cysts	CHF (rare)	Malformations of the face, oral cavity, and digits
Glomerulocystic disease	*PKD1; TCF2; HNF1B*	Enlarged; normal or hypoplastic kidneys	CHF (with *PKD1* mutations)	Diabetes; hyperuricemia
Jeune syndrome (short-rib thoracic dysplasia [SRTD])	*SRTD1-SRTD20*	Cystic dysplasia	CHF; Caroli syndrome	Short stature; skeletal dysplasia; small thorax; short limbs; polydactyly; hypoplastic pelvis
Renal-hepatic-pancreatic dysplasia (RHPD)	*NPHP3; NEK8*	Cystic dysplasia	Intrahepatic biliary dysgenesis	Pancreatic cysts, dysplasia, and/or fibrosis; splenic abnormalities; situs inversus
Zellweger syndrome	*PEX1–3;5;6;10;12–14;16;19;26*	Renal cortical microcysts	Intrahepatic biliary dysgenesis	Hypotonia; seizures; agenesis/hypoplasia of corpus callosum; characteristic facies; skeletal abnormalities; neonatal death

[a] CHF – congenital hepatic fibrosis

disorder of glycosylation type 1a (CDG1A), which has a severe, pleiotropic phenotype.

Genetic Testing

Molecular diagnostic analysis is rapidly becoming the gold standard for diagnosing ARPKD and distinguishing this disorder from the large number of phenocopy disorders or syndromes [9]. Available data indicates that compound heterozygous or homozygous *PKHD1* mutations have been identified in approximately 80% of patients suspected of having ARPKD, with phenotypes ranging from perinatal demise to disease presentation in young adults. At least one *PKHD1* mutation has been found in more than 95% of families screened [9]. However, in patients with only one *PKHD1* variant or without any detectable *PKHD1* mutations, phenocopy disorders, e.g., due to mutations in *PKD1* or *HNF1B*, should be considered [41].

In practice, screening a panel of genes rather than analysis of *PKHD1* alone has become the preferred diagnostic approach [9]. Advances in next-generation sequencing (NGS) now enable simultaneous analysis of a large number of genes in a single test at relatively low cost. While whole exome or whole genome-based screening may become the standard for genetic testing in the near future, at present, targeted NGS panel testing is the most efficient diagnostic approach. Whichever methodology is used, the testing strategy should be designed to detect copy number variations (CNVs) such as heterozygous deletions (for example, in *HNF1B*) and to cover complex genomic regions, such as *PKD1*. Clinical genetic testing laboratories are summarized at the NIH-sponsored Genetic Testing Registry, www.ncbi.nlm.nih.gov/gtr.

Preimplantation Genetic Diagnosis (PGD)

In families who have had a previous child with severe ARPKD, the high recurrence risk (25%) often prompts interest in either prenatal diagnosis or PGD for future pregnancies. PGD requires prospective identification of the *PKHD1* mutations transmitted from each parent. The couple then must undergo in vitro fertilization. The resulting embryo is biopsied, with removal of 1–2 embryonic cells for genetic testing. PGD has successfully guided the birth of unaffected infants in at risk families [46].

Protein Function and Pathophysiology

FPC, the product of the *PKHD1* gene, is a 4074 amino acid, single-membrane spanning protein with a long extracellular N-terminus and short cytoplasmic C-terminus, that appears to have multiple isoforms [33]. During fetal development, *PKHD1* is broadly expressed in the neural tube, bronchi, primordial gut, early ureteric bud, mesonephric tubules, adrenal cortex, and immature hepatocytes, suggesting a role in organ development and tubular morphogenesis [12, 47]. In adult tissues, *PKHD1* is expressed predominantly in the kidney (mostly in collecting ducts and thick ascending loops of Henle), liver (localized to bile ducts), and pancreas [48, 49]. In renal tubular and biliary epithelial cells, FPC localizes to the apical membranes as well as to the primary cilia/basal body [33, 48, 50] and mitotic spindle [51].

FPC is secreted in exosomes and appears to be posttranslationally modified [52]. A subset of membrane-bound FPC undergoes Notch-like proteolytic processing, with shedding of the extracellular domain into the tubular lumen and nuclear translocation of the C-terminus, where it may play a role in downstream signaling [53–55]. However, predictions regarding the nuclear function of the cytoplasmic C-terminus are confounded by a mouse model that lacks most of the C-terminus and is phenotypically normal, without renal or hepatic disease even when aged [49].

The function of FPC is slowly coming into focus. In animal studies, mice harboring mutations in both *Pkhd1* and either of the ADPKD genes (*Pkd1* or *Pkd2*) display cystic phenotypes that are much more severe than those expressed with either mutation alone, indicating genetic interactions in vivo [56–58]. However, a direct physical interaction between FPC and the *PKD1* gene product, PC1, has not been demonstrated. Moreover, the functional significance of the reported interaction of FPC with the *PKD2* gene product, PC2, is uncertain since *Pkhd1* mutant mice lacking the FPC-PC2 interaction domain are phenotypically normal [49].

FPC appears to indirectly regulate the function of the C2-WWW-HECT domain E3 family of ubiquitin ligases by affecting the subcellular localization of NDFIP2, a protein implicated in regulating the trafficking and function of the E3 ubiquitin ligase family [59]. This protein family includes SMURFs and NEDD4, which are known to regulate the activity of RhoA, TGF-β signaling, and ENaC activity, all of which have been reported to be upregulated in ARPKD renal and biliary epithelial cells. These data may provide a unifying explanation for the observed changes in cytoskeletal structure, increased fibrosis, and enhanced sodium absorption and hypertension, but the mechanism through which FPC modulates NDFIP2 function remains unknown.

The reported localization of FPC to the basal body/primary cilium provides another intriguing, but incomplete insight into its function. As noted, FPC, DZIP1L, and other proteins associated with the hepatorenal fibrocystic diseases (e.g., ADPKD, nephronophthisis, and Meckel, Joubert, and Bardet-Biedl syndromes) also localize to these structures (Fig. 3). Taken together, these

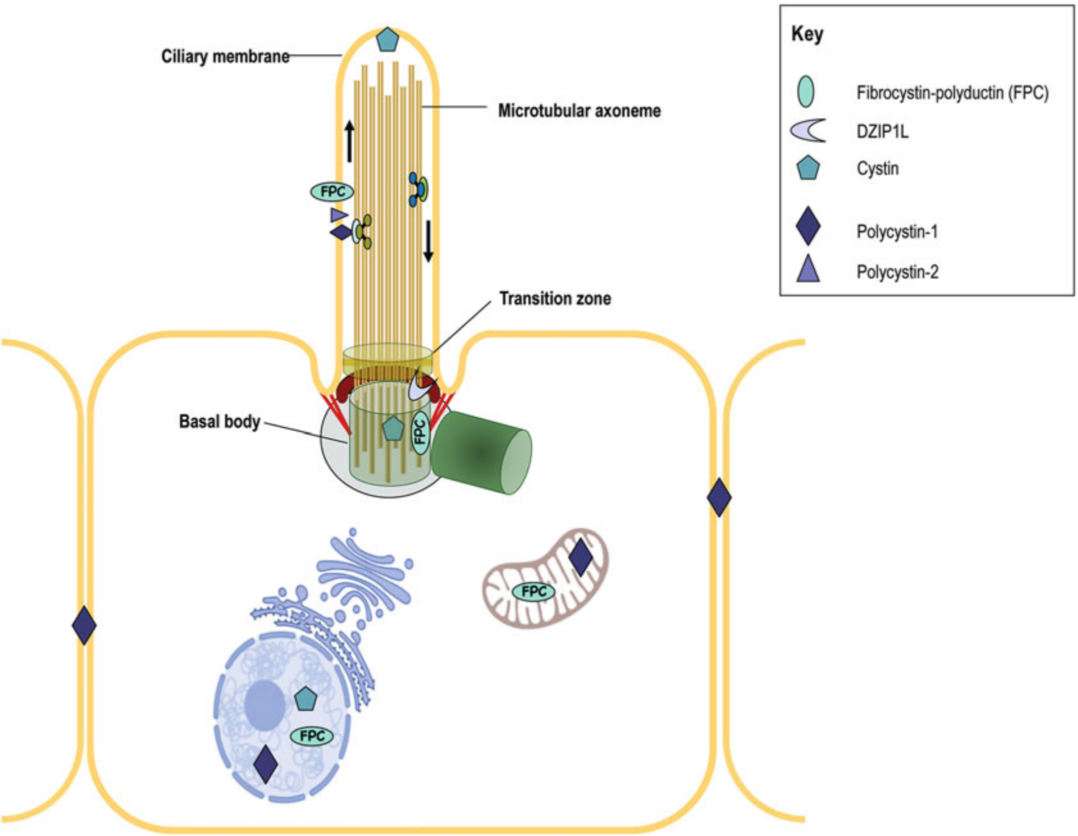

Fig. 3 Cellular localization of ARPKD-relevant proteins. FPC localizes to several subcellular compartments. These include the basal body/primary cilium, where polycystin-1, polycystin-2, cystin, and other proteins associated with the hepatorenal fibrocystic diseases also have been detected. FPC colocalizes with DZIP1L in the transition zone and cystin in the basal body. FPC and PC-1 have also been localized to the mitochondria and PC-1 to cell-cell junctions. The carboxy-terminus of FPC appears to undergo regulated translocation to the nucleus, where like cystin and PC-1, it may be involved in transcriptional regulation

data suggest a central role for the primary cilium in the development and maintenance of renal tubular architecture, perhaps via mechanisms such as flow sensing and establishment of planar cell polarity, although the specific function of FPC in any of these processes remains undefined [60].

As in ADPKD, the cAMP signaling system is activated in ARPKD (reviewed in [61]), as is the mTOR pathway [62]. In addition, new data implicate bioenergetic remodeling in both ADPKD and ARPKD pathogenesis [63, 64].

However, translating any of these observations to human clinical trials has been confounded by incongruities between human disease and experimental models as well as the lack of noninvasive markers to track disease progression and assess outcomes. For example, while agents that target cAMP activation effectively attenuated cystic disease progression in the *pck* rat (orthologous ARPKD model) [65], mTOR inhibition in this rat model failed to impact disease in either the kidney and liver disease [66]. Thus, current efforts are focused on optimizing preclinical studies with targeted therapeutics in experimental models and developing noninvasive markers for human clinical trials, which assess progression endpoints and are acceptable to regulatory agencies.

Clinical Disease Course and Clinical Management

ARPKD is typically diagnosed in the perinatal period, and despite dramatic advances in neonatal care, is still associated with significant morbidity and mortality. Current knowledge about ARPKD clinical manifestations is derived primarily from cohort studies, and thus the conclusions are greatly influenced by the way cohorts were selected. Some studies relied on recruitment from pediatric nephrology centers, while other reports were based on single-center experience. Furthermore, the genetic resolution of the disease-causing gene was not possible in earlier cohort studies or relied on linkage analysis for presumptive diagnosis. Thus, these cohorts likely included patients with phenocopy disorders due to mutations in other renal cystic disease genes. Nevertheless, there can be value in studies that relied solely on the clinical diagnosis and some cases, comparison of sub-cohorts with and without genetic findings may yield informative insights.

Most management recommendations remain opinion-based, with treatment strategies focused on ARPKD associated findings, such as hypertension [4, 5]. An 2014 international consensus report summarized management recommendations for ARPKD [4] and a more recently, a second international group has provided guidelines for perinatal management of cystic kidney diseases in general [5].

Perinatal Period

ARPKD is currently diagnosed primarily in the latter stages of pregnancy or at birth, with enlarged, hyperechogenic kidneys. As noted, distinguishing ARPKD from other phenocopy disorders can be challenging. Extrarenal manifestations can be a help to guide the clinical diagnosis [5]. Normal antenatal ultrasound findings do not exclude ARPKD, especially early in pregnancy. Oligo- or anhydramnios may develop as a result of renal functional impairment and portend worse neonatal outcomes [16]. In the presence of oligo- or anhydramnios, severely affected fetuses may develop the “Potter” phenotype with pulmonary hypoplasia, contracted limbs with club feet, and a characteristic facies. Pulmonary hypoplasia still poses a severe clinical challenge and often dictates postnatal survival [5]. Serial amnio infusions have been administered in a small number of patients, but the risk-benefit of these interventions remains to be determined. After birth, severely affected infants may require aggressive ventilatory management and pneumothoraces may become a complicating issue [5].

Current recommendations suggest that delivery of infants with suspected ARPKD should be arranged for centers with specialized neonatal and pediatric nephrology teams [4, 5]. Families of severely affected neonates may require counseling to help determine whether to proceed with aggressive care versus opt for palliative treatment. Decisions to start, withhold, or discontinue treatment often depend on a combination of patient-specific issues and family-specific factors. Multidisciplinary support and shared decision-making that is supported by a formalized ethical framework may be helpful [5].

Overall, advances in pediatric and neonatal intensive care, including sophisticated ventilation strategies, use of surfactant, improved feeding methods, as well as improved renal replacement therapy (RRT) in very young children have improved survival rates for ARPKD patients, many of whom now reach adulthood. While previous estimates suggested that up to 30% of ARPKD neonates die shortly after birth due to respiratory insufficiency [1, 30], a recent EHR-based analysis in the USA calculated a 79% perinatal survival rate [10]. Reports based on cohorts who were born in the 1990s and early 2000s have demonstrated 10-year survival rates of up to >90% for those ARPKD patients who survived the first month of life [1, 5].

Kidney Disease

Prenatal prognostic markers that predict postnatal kidney function are not well-established for

ARPKD. In the largest cohort study reported to date, involving 385 patients, enlarged kidneys, kidney cysts, and oligo-/anhydramnios were identified as sonographic predictors of early postnatal dependency on renal replacement therapy [16]. Documentation of low amniotic fluid volumes, prenatal renal enlargement, low Apgar scores, and requirement for postnatal respiratory support were independently associated with an elevated hazard ratio for dialysis dependency in the first year of life. These data may provide the basis for a predictive algorithm that identifies subgroups of patients at high-risk for an early severe kidney phenotype [16].

While decreased kidney function is common in ARPKD neonates, kidney failure rarely is a cause of neonatal death. Urine output and serum electrolytes should be monitored in neonates with significant kidney disease, e.g., those with a history of oligohydramnios [5]. Kidney function may improve during the first months of life, with subsequent progressive loss of function that can be highly variable among affected patients. A single study suggests that loss of renal function may accelerate after 10 years of age [67]. Overall, eGFR decline in ARPKD children is not substantially different from the rate of functional decline in children with chronic kidney disease (CKD) due to other underlying diseases. Perinatal clinical presentation seems to portend poorer kidney outcomes than that observed in children with later diagnosis. In one cohort, 25% of the children diagnosed in the perinatal period required kidney replacement therapy by 11 years of age, whereas for children diagnosed after the first year of life, only 25% required transplantation by 32 years of age [24].

Kidney disease management should follow the established pediatric CKD guidelines [4]. Systemic hypertension occurs in up to 80% of ARPKD patients, often developing in the first months of life [30, 31]. The precise pathogenic mechanisms are not well understood, but available data suggest that systemic hypertension in ARPKD is due to dysregulation of tubular sodium and water handling, resulting in volume overload [4]. Hypertension may improve after the first year of life, potentially in parallel to the decline in kidney function.

Antihypertension management can be very challenging and require the use of multiple drug classes. Antagonizing the renin angiotensin system with ACE inhibitors or AT1 receptor blockers is recommended as first-line therapy, based the effectiveness in the general pediatric CKD population and preclinical data indicating activation of RAS in experimental PKD models [4]. General principles of antihypertensive treatment apply as evidence remains too limited for ARPKD-specific recommendations.

Beta blockers may be considered in patients with evidence of CHF and portal hypertension. Loop diuretics could potentially lead to an upregulation of serum vasopressin levels due to the underlying urinary concentration defect and thus, could potentially trigger cyst growth. However, in many ARPKD patients, diuretics are required. Amiloride or similar agents may be considered given experimental data that show ARPKD cyst-lining cells absorb Na by a pathway that is modestly amiloride-sensitive [68].

Hyponatremia is frequently observed in ARPKD patients in the first weeks to months of life, but is often transient and resolves over time [30, 31]. Fluid overload should be avoided and care should be taken to avoid excessive sodium supplementation that might aggravate arterial hypertension [4]. Urinary tract infections are common in ARPKD children and have been reported in up to 50% of patients, with higher incidence in females [30].

ESKD has been reported in about 30% of ARPKD patients by the age of 10 years and about 40–60% of patients by the age of 20 years [31, 32]. Peritoneal dialysis and hemodialysis, as well as isolated kidney transplantation and combined liver and kidney transplantation have all been successfully used in ARPKD patients. Selecting the right modality for an individual patient depends on multiple factors, including the age of the patient, the experience of the center, and the family context. RRT is the standard approach even in neonates and young infants, although it requires an intensive personnel engagement involvement and individualized approaches. A large international cohort reported that the overall survival for RRT in neonates and infants was 81%

after 2 years [69]. In a North American study, survival was about 80% after 3 years in infants who initiated RRT in the first month of life, with 85% survival for a subgroup that initiated RRT later during the first year of life [69, 70].

The International Pediatric Peritoneal Dialysis Network (IPPN) registry systematically compared peritoneal dialysis in young children with ARPKD ($n = 79$) with two matched control groups with ESKD due either to congenital nephrotic syndrome (CNS) ($n = 79$) or congenital anomalies of the kidney and urinary tract (CAKUT) ($n = 158$) [71]. There was no significant difference in overall survival between ARPKD and CNS patients, while CAKUT patients had better overall survival. Importantly, there were no differences in the technical issues among the groups and peritoneal dialysis only required minor adaptions of prescription for ARPKD patients.

Uni- or bilateral nephrectomies are sometimes considered in infants with ARPKD, based on the assumption that massively enlarged kidneys can compromise respiratory management or nutritional support. However, the evidence base for these interventions is limited [4]. Furthermore, potential benefits need to be carefully weighed against risks and sequelae of nephrectomies. This includes issues related to unilateral nephrectomy, such as accelerated decline in renal function due to the reduction of nephron mass and rapid growth of the contralateral kidney, requiring a rapid second nephrectomy (summarized in [72]). The European ARegPKD study found that timing of nephrectomies may be an important determinant of untoward consequences [73], with bilateral nephrectomies in the first 3 months of life and hypotensive episodes emerging as independent risk factors for neurological complications later in life. Interestingly, the neurological outcome was better in a group of patients that underwent their second nephrectomy in the months 4–15 of life. These data suggest that a cautious approach is warranted when considering very early bilateral nephrectomies.

As for other causes of CKD in childhood, renal transplantation is the RRT modality of choice for ARPKD patients. Overall patient and graft survival in ARPKD patients corresponds to pediatric renal transplantation in general and this structural renal disease does not recur after transplantation. Nephrectomy of native ARPKD kidneys may be required prior to or during transplantation. Post-surgery, heightened vigilance for sepsis is warranted, as cholangitis and biliary sepsis are a major cause of mortality in ARPKD patients following isolated kidney transplantation [74, 75]. Considerations about combined liver and kidney transplantation are discussed below.

Biliary Tract Disease

As more ARPKD patients survive the perinatal period and renal disease management prolongs patient survival, liver disease is steadily becoming a major clinical issue. Liver involvement is an invariant feature of ARPKD [4, 14]. Therefore, ARPKD patients require interdisciplinary management that includes regular hepatological follow-up for progressive congenital hepatic fibrosis or Caroli's syndrome [4].

On sonography, liver parenchyma is typically inhomogeneous, the liver may be enlarged, and dilated bile ducts may be evident [17, 29, 32, 76]. Various elastography methods have been used to quantify liver fibrosis. Acoustic radiation force impulse has shown higher liver and spleen shear wave speed in ARPKD patients as compared to healthy controls, with the left liver lobe imaging having the highest sensitivity and specificity in distinguishing ARPKD subjects with portal hypertension [76]. Magnetic resonance imaging may become a useful modality to quantifying the extent of CHF [77], and provide important information on intra- and extrahepatic bile ducts, e.g., within the frame of an MRCP. Furthermore, novel magnetic resonance imaging applications are being evaluated for evaluating renal cystic disease progression [78].

Hepatocellular function is usually preserved, but progressive portal hypertension and episodes of cholangitis may complicate management [4, 29, 32]. Portal hypertension may result in splenomegaly and the development of collateral circulation. Hypersplenism may result in pancytopenia. Varices involving the esophagus, stomach, and anus may develop. Bleeding, particularly from esophageal varices, may be life-threatening and regular endoscopic evaluation including sclerotherapy or variceal banding may be required [4]. Transjugular intrahepatic portosystemic shunting (TIPS) has been successfully applied in some patients [79]. However, for patients with significant CKD, the risk of developing hyperammonemia after TIPS must be considered.

Laboratory evaluation typically reveals no biochemical evidence for hepatic dysfunction [4]. Serum liver transaminases are rarely elevated, while biliary markers, e.g., *gamma-glutamyl* transferase (GGT), can be markedly elevated. Thrombocytopenia was the best predictor of portal hypertension and splenomegaly in a cohort of 73 patients [29]. Among young adults with ARPKD, a high number of patients had different types of hepatic involvement with hepatosplenomegaly, thrombocytopenia, and inhomogeneous liver parenchyma on ultrasound being the most common findings [32]. Liver-associated issues gradually progress over the course of childhood and can represent a significant management issue in transitioning care to adult health systems.

Cholangitis is a potentially severe complication of ARPKD-related liver disease and diagnosis can be challenging. Therefore, unexplained fever in a child with ARPKD should prompt aggressive evaluation for cholangitis, particularly in patients following isolated kidney transplantation. Studies should include GGT, inflammatory markers, and cultures of blood and urine. Liver ultrasound examination may be useful. In cases of confirmed cholangitis, aggressive antimicrobial treatment is indicated. In general, antibiotic prophylaxis is not recommended [4].

In patients with CHF from a variety of causes, there is an increased risk of hepatobiliary carcinoma. This risk should be considered in the management of adult ARPKD patients, but is a very rare complication in children and young adults with ARPKD [4, 80, 81].

Transplantation

ARPKD is one of the two major pediatric indications for combined liver and kidney transplantation when a patient has marked CKD and substantial liver involvement, due to severe portal hypertension or recurrent cholangitis [82–85]. One report has described better kidney graft function after combined kidney and liver transplantation from the same donor, which would permit a less intensive immunosuppression regimen [86]. These factors must be weighed against the increased risk of combined organ transplantation and the limited number of centers that are equipped to undertake this aggressive intervention. For example, recent analysis of ARPKD patients in the ESPN transplant registry identified a 6.7-fold increased age- and sex-adjusted mortality risk over a 5-year follow-up for those undergoing combined liver and kidney transplantation ($n = 32$) compared to isolated kidney transplantation ($n = 163$) [82]. This retrospective analysis revealed that some patients undergoing combined transplantation had limited evidence of clinically significant liver disease and there was no detectable benefit for renal graft survival in this cohort. These data demonstrate the importance of careful individual decision-making in these cases. Various algorithms to guide decision-making regarding combined transplantation in ARPKD patients have been proposed but more data are needed [82–85].

Additional Features

In addition to neonatal respiratory insufficiency and fibrocystic liver disease, additional extrarenal disease manifestations must be considered in the management of ARPKD patients. Failure to thrive is a general concern in children with early-onset CKD. In ARPKD, enlarged kidneys, uremia, and respiratory challenges due to pulmonary hypoplasia may impact feeding and adequate nutrition. There is debate about whether growth delay is a primary feature of ARPKD, with two large registries finding growth delays in up to 25% of patients, whereas analysis of 22 ARPKD patients in the CKiD cohort did not identify a disease-specific effect of ARPKD on growth [31, 87, 88].

While gastrostomy tubes are often placed in children with CKD to facilitate adequate nutritional intake, in ARPKD patients, there are specific concerns about secondary splenic injury or the increased risk of bleeding due to portal hypertension [89]. A recent European ARegPKD Consortium survey of clinicians managing ARPKD patients found that most centers supported gastrostomy tube placement if clinically indicated. The reported complications were generally comparable to those in non-ARPKD patients undergoing the same procedure [90].

In ADPKD patients, the most feared extrarenal complication is the development of intracranial aneurysms. For ARPKD patients, the data are very limited [4]. While there are a growing number of case reports on vascular aneurysms (intra- and extracranial) in ARPKD patients, these appear to be rare complications of a rare disease, particularly for children and young adults [91, 92]. A specific screening protocol has not been recommended, but a low threshold for corresponding imaging seems justified.

The toll of CKD, arterial hypertension or hypotension (e.g., after nephrectomies), liver disease, and lung disease, on neurocognitive development in ARPKD was evaluated in a recent CKiD study. Intellectual functioning, academic achievement, attention regulation, executive functioning, and behavior were comparatively evaluated in 22 ARPKD children versus 44 children with other underlying causes of mild-to-moderate CKD. Children were matched for glomerular filtration rate, age at study entry, and age at diagnosis. There was no evidence for neurocognitive dysfunction in ARPKD patients [93].

Finally, as a chronic disease that typically manifests early in life and progresses through childhood, ARPKD can be challenging for both the impacted child and the family. Clinical management needs to take into consideration these psychological issues and the need for psychosocial support cannot be overstated. In addition to the care team, support is available from patient advocacy groups, e.g., PKD International in Europe or the PKD Foundations in the USA and Canada.

Future Horizon

ARPKD is a multifaceted disorder which requires expert, multidisciplinary management. Much has been learned over the past few decades about the genetics and pathobiology of this disorder. Patient survival has improved remarkably due to advances in supportive therapy, dialysis, and transplantation. The recent development of harmonized international ARPKD registries [10, 94], next-generation sequencing platforms, and new imaging modalities are laying the foundational framework for predicting postnatal outcomes, characterizing patient subsets, clarifying how genetic variants impact disease expression, and devising new strategies to monitor disease progression. In addition, there is increasing recognition that mechanistic pathways in ARPKD in large part overlap with ADPKD. Taken together, the near horizon holds the promise of developing predictive/prognostic markers and initiating clinical trials with targeted therapeutics. The ultimate goal is to identify disease-specific therapies that mitigate the inexorable progression of ARPKD-related morbidities.

Abstract

Tuberous sclerosis complex (TSC) affects every organ system. Throughout the patient's lifetime, the renal manifestations become more serious. While renal disease can be life threatening in the adult with TSC, the opportunity to modify the disease course is during the pediatric time frame. Recent advances in cell biology have translated into targeted therapy for TSC renal disease and have revealed novel insights about the renal response to disease. Proper surveillance and treatment can significantly reduce the renal disease burden and prolong the duration and increase the quality for the patient.

Introduction

Tuberous sclerosis complex (TSC) is a genetic disorder characterized by abnormal development and post-natal cellular proliferation in many parts of the body. The resulting tumors commonly occur in the skin, brain, kidneys, lungs and other organs, and in some cases leading to significant health problems. Virtually all affected people have skin abnormalities, including hypopigmented macules, subungual fibromas, and a Shagreen patch. The majority of TSC patients also have brain involvement that can lead to neuropsychiatric disorders including anxiety, depression, hyperactivity, aggression, psychiatric conditions, intellectual disability, and autism spectrum disorder. Mostly in childhood and young adulthood, patients can develop a subependymal giant cell astrocytoma (SEGA), and the incidence greatly drops off after the age of 36 years. The frequency of diseases also increases with age in some organ systems. In TSC, the prevalence of LAM increases with age reaching up to 80% in women aged 40 years [26]. Renal disease in TSC likewise increases with age. Recognition of the remarkably varied disease manifestations and severity is confounded by the rarity, interfering with accurate diagnosis and treatment of affected patients. Over 80% of affected children and all adult postmortem samples [69] were found to have renal disease, most commonly renal angiomyolipomata and cysts. Premature decline of glomerular filtration rate (GFR) occurs in ~40% of patients with TSC [10], and can occur in the absence of angiomyolipomata bleeding or interventions. TSC associated renal disease was the leading cause of death in those clinic populations [51, 66].

Genetics

Tuberous sclerosis complex, an autosomal dominant genetic disorder affecting every organ system, exhibits a birth incidence of ~1:5800 and affects approximately one million patients worldwide [24, 77]. Proper diagnosis often will be missed if one uses the outdated Vogt's triad for TSC (facial angiofibromas, developmental delay, and intractable epilepsy) because less than 40% of affected patients exhibit these classical features [48]. Only about half of patients with TSC exhibit cognitive impairment, autism, or other behavioral disorders [48]. There are two loci associated with TSC, the *TSC1* gene on chromosome 9 and the *TSC2* gene on chromosome 16. The identification of the *TSC2* gene location was facilitated by an astute genetic observation in a family with autosomal dominant polycystic kidney disease (ADPKD). The polycystic disease was caused by a balanced translocation involving the *PKD1* gene. The child in the family who had both ADPKD and tuberous sclerosis complex inherited the unbalanced translocation, the mapping of which aided in the positional cloning of the TSC2 gene [35].

Tuberous sclerosis complex generally is thought to be phenotypically expressed by a second somatic silencing event of the non-mutant allele, either through a second somatic mutation or other possibly silencing mechanisms. Both TSC and autosomal dominant polycystic kidney disease are phenotypically expressed due to a second-hit, or somatic mutation mechanism [21, 43]. The kidney disease associated with chromosome 16, specifically the *PKD1* and the *TSC2* loci, account for a majority of their respective diseases, and exhibit a more severe phenotype compared to the disease associated with the other loci (*PKD2* and *TSC1*). This association of the short arm of chromosome 16 with more severe disease appears to have a molecular underpinning. The *PKD1* and *TSC2* genes are adjacent, in a tail-to-tail orientation, and the *PKD1* gene contains an intronic sequence that has unique structural properties [19] that can predispose to mutation. This odd *PKD1* sequence interferes with DNA replication and causes DNA double-strand breaks resulting in mutations [50, 61]. Synergizing with this predisposition to DNA double-strand breaks, the renal microenvironment also inhibits recognition of DNA damage [30–32].

Clinical Aspects and Treatment of TSC Renal Disease

General Clinical Aspects

Multidisciplinary Care

Due to the many manifestations of TSC disease and the serious complications, management requires the expertise of multiple medical disciplines [4]. To adequately care for patients, consensus guidelines recommend a multidisciplinary care approach [49]. The use of multidisciplinary teams is beneficial in treating other complex diseases, such as cancer. The care of the renal patient really relies on experience.

Chronic Kidney Disease

By their mid 50s, 41% of patients with TSC have exhibited stage 3 or greater chronic kidney disease (CKD), compared to 3% of the general population [10, 46]. Although, the risk of end stage renal failure in which families opt for renal replacement therapy appears to be about ten-fold lower [34]. Therefore, TSC patients with renal disease are at an increased risk for premature cardiovascular disease [56] and may succumb before they reach end stage renal failure. There are multiple potential causes for this premature loss of GFR, including acute kidney injury from renal hemorrhage, loss of normal renal parenchyma following embolization or surgery, hypertension, and replacement of normal renal cells with angiomyolipomata or cysts. Also, it has been suggested that damage is caused to normal renal tissue by multiple angiomyolipomata. GFR can be normal even when there is no recognizable renal parenchyma on imaging. Impaired kidney function has been identified more commonly in patients who had undergone embolization (29%) than in those who had not (10%). However, this finding may represent a selection bias because of the high burden of angiomyolipomata in those who subsequently needed embolization [62]. Hopefully mTORC1 inhibitor therapy will ameliorate renal angiomyolipomata and will improve long-term outcomes of renal function. Preliminary evidence of a very low complication rate—including low levels of renal impairment—in the TOSCA cohort support that this is a useful strategy [48].

Hypertension

Hypertension is more common in patients with renal TSC than in the general population [44]. Hypertension is a known risk factor for progression of renal scarring and accelerates GFR loss in patients with renal disease if not treated appropriately. Standard recommended blood pressure targets for adult TSC patients is ≤130/80 and appropriate 70% for age adjusted targets for children [36]. There is concern about using angiotensin converting enzyme inhibitors (ACEIs) in those TSC patients taking mTORC1 inhibitors based on a possible increase incidence of angioedema in kidney transplant patients taking both [33]. However, ACEIs and angiotensin receptor blockers are extremely useful in this population and may suppress the growth of angiomyolipomata [68] and cysts [63]. Angioedema due to the combined administration of mTORC1 inhibitors and angiotensin converting enzyme inhibitors has not been reported in the TSC population as a drug limiting problem, and they can be used concurrently with caution [28].

Specific Aspects Including Diagnosis, Surveillance, and Treatment of TSC Associated Renal Disease

There are specific aspects of TSC renal care that deserve attention. These include the renal angiomyolipomata and cystic disease. While the hemorrhage risk of angiomyolipomata and the need for treatment is becoming better understood, the health risk of TSC renal cystic disease is still less appreciated.

Angiomyolipomata

Angiomyolipomata detection in patients with TSC increases from 8.8% in patients less than 2 years of age to 78.9% in those patients greater than 40 years of age [11]. Likewise, the number of patients requiring intervention also rises from 1% in the under 2 year-old up to 48.6% in those over 40 [48].

However, the imaging modality is a source of confusion. About a third of TSC-associated angiomyolipomata seen in a TSC Center of Excellence with expertise in TSC Nephrology have significant fat-poor components. Because these fat-poor lesions have similar tissue density as renal parenchyma, they have echotexture similar to kidney and are often not identified using ultrasound. This reason is part of the rationale behind the International Consensus Guidelines that recommend MRI as screening for TSC patients [49, 58]. Because at least half of the patients affected with TSC will have cystic disease on MRI, it is common for some patients to have a solid mass that is in close proximity to cystic components. In the general population, such findings raise concern for renal cell carcinoma. They should not raise the same level of concern in the TSC patient population because fat poor angiomyolipomata are much more common than the rare renal cell carcinoma. Such lesions can safely be serially assessed for growth to help distinguish fat-poor angiomyolipoma from malignancy [62].

Lesion hemorrhage is a potential complication of angiomyolipomata which had historically been reported to occur in 25–50% of patients [45, 57]. More recently, it has been reported to occur in about 30% of patients in a larger population-based study of patients not having active surveillance [47]. One explanation for this is the propensity for aneurysm formation which involves the vascular pericytes and their larger vessel equivalent, the adventitial cells. Given their likely role in the renal disease [68], it follows that such cells, with a loss of TSC gene function, would be compromised in their normal function of choreographing vessel structure and function, facilitating aneurysm formation. Aneurysms larger than 5 millimeters are at higher risk of rupturing [74]. They are best approached using arterial embolization plus a corticosteroid taper over a week or two to reduce the post-embolization syndrome [11]. Angiomyolipomata are detectable at a younger mean age in patients with *TSC2* mutations compared to *TSC1* (13 years vs. 24 years) [48]. Intervention is required more often in patients with a *TSC2* mutation compared to *TSC1* (27% vs. 13%) and have equal prevalence between males and females with TSC. The risk of aneurysms rupturing, resulting in hemorrhage is also associated with lesion size; those 30 mm in diameter and still enlarging are at the greatest risk.

The recommendations for treatment have radically been altered because of discoveries in cell biology leading to clinical trials. A decade ago, recommendations centered on embolization and, if required, urologic surgery. Now, the International Guidelines for surveillance and management of TSC recommend preemptive treatment of enlarging angiomyolipomata that are >30 mm in diameter with an mTORC1 inhibitor to prevent hemorrhage [49]. The soundness of this recommendation can be appreciated by considering that a proactive experience of monitoring and preemptive embolization did improve the high risk of bleeding, but there was still significant renal morbidity and mortality. Eijkemans et al. reported 57 patients that required two or more embolization procedures, 16 requiring nephrectomy, 7 dialysis, and 7 transplantation, and that of the 29 deaths, 9 were due to renal causes [34]. With the advent of mTOR inhibitors replacing embolization as first choice for preemptive therapy, complications such as hemorrhage have been reduced to just 5% of 2216 subjects in one large study [48]. A series of phases 2 and 3 studies has shown that mTORC1 inhibitor therapy is highly effective at stabilizing or shrinking angiomyolipomata in both adults [12, 13, 27] and children [14] in the short term, and preventing bleeding and preserving renal function in both groups in the long term [16].

In the setting of TSC, angiomyolipomata are classified as benign lesions, though non-TSC varieties can be aggressive [2], and there are rare reports of TSC angiomyolipomata exhibiting malignant features [1]. In the non-TSC patients, the malignant angiomyolipomata are associated with mutations in MITF transcription family genes that are known to have a significant link to malignancy [29]. Although angiomyolipomata are often begin in childhood TSC patients, the majority continue to grow life-long. Most commonly, they involve the kidney but also the liver, local lymphatics or elsewhere, often in the abdomen.

Table 1 **Sages of angiomyolipomata and cystic disease.** Angiomyolipomata stages are defined by the number and size of the lesions as well as the renal morphology. This latter component helps catch the infiltrative lesions. Cystic disease is described by the number of cysts or degree of renal involvement

Stage	**0**	**1**	**2**	**3**	**4**	**5**	**6**
Angiomyolipomata							
Number	None	1 to 4	>5	All <5	>5	>5	>5
Size	*None*	*<3 cm*	*<3*	*1 > 3 cm*	*2 to 4 are >3 cm*	*>5 are >3 cm*	*1 > 5 cm*
Morphology	*Normal*	*Normal*	*Normal*	*Intact*	*Intact*	*Recognizable*	*Nonrecognizable*
Cystic disease							
Polycystic	0	<2	3–6	7–10	11–20	21–30	>31
Cortical cystic	0	1–10	11–20	21–30	31–40	41–50	>51
Multicystic	0	1–10	11–20	21–30	31–40	41–50	>51
Focal cystic	0	1 ray	2 ray	3 ray	4 ray	5 ray	>5 ray
Microcystic	0	10%	20%	30%	40%	50%	>50%

Guidelines for surveillance and treatment of angiomyolipoma in patients with TSC are straight forward. In order to avoid failing to detect fat poor lesions, MRI is recommended for screening and monitoring renal angiomyolipomata at diagnosis and every 1–3 years following diagnosis [58]. A clinical system of scoring for angiomyolipomata (Table 1) is useful, especially given the regression induced by mTORC1 inhibitor therapy [15]. Other aspects of TSC associated disease are also responsive to mTORC1 inhibition. The brain lesion, subependymal giant cell astrocytoma (SEGA), that occurs in about 20% of patients with TSC respond to mTORC1 inhibitors [37], as does the lung disease, lymphangioleiomyomatosis (LAM) [12, 55].

Cystic Disease

TSC renal cystic disease is identified by conventional MRI in approximately 50% of patients. The size of the renal cysts in TSC renal disease range from the microscopic glomerulocystic to a polycystic renal phenotype associated with the TSC2/PKD1 contiguous gene syndrome. There are five basic patterns of cystic disease described (Table 1, Fig. 1), and there seems to be a cortical/column of Bertin predilection early on in the disease process. While there are no approved treatments of TSC associated renal cystic disease, blood pressure control using angiotensin converting enzyme inhibitors or angiotensin receptor blockers has been adopted, as this was effective in the HALT trial that has tested these drugs in ADPKD [64]. Small cystic lesions can also be mTORC1 responsive [17]. In order to communicate the actual cystic disease, the disease patterns are described below.

TSC Polycystic Kidney Disease

This manifestation, accounting for about 2% of TSC renal disease, is most often associated with a deletion involving the adjacent *TSC2* and *PKD1* genes on chromosome 16p13, and there is a high frequency of mosaicism [23]. Hypertension is often discovered by the second week of life but can take several months to develop, and sometimes it does not develop. Because of significant renal parenchyma disruption, these children sometimes develop a urinary concentrating defect very early. The lining of these cysts appears to be intercalated cells, and may arise from a mechanism distinct, at least in part, from ADPKD [17]. Because the kidney mass can be so great, learning to walk as a developmental milestone may be delayed purely due to mechanical issues. Nocturnal enuresis is often prolonged because of the concentration defect, and ddAVP should be avoided given the unknown effect it may exert on cyst growth. If blood pressure is well-controlled, patients often maintain renal function until young adults. mTORC1 inhibition in this form of cystic disease will only affect the small cysts and have no effect on the large ones.

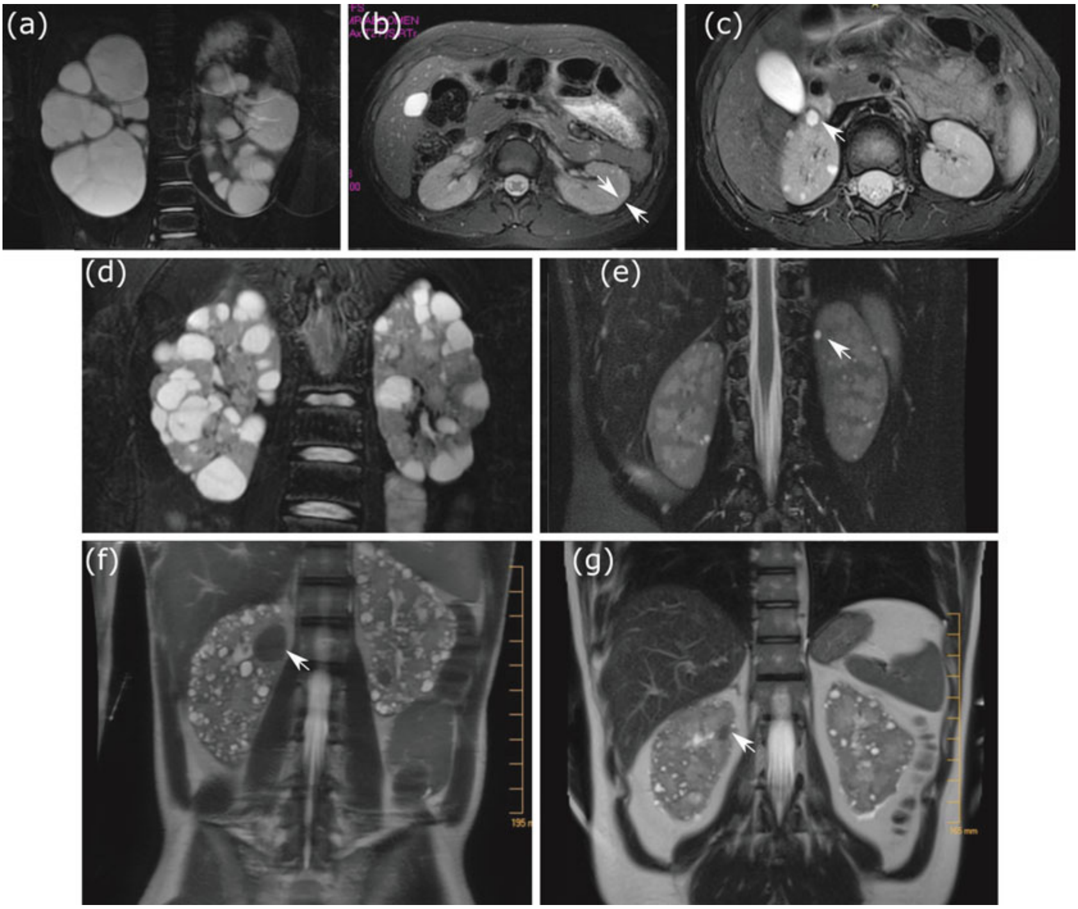

Fig. 1 Phenotypes of TSC renal cystic disease. (**a**) Polycystic variety. The white cysts are easily seen in the T2 fat suppressed image (**b**) Microcystic disease. Note, the cortex is too 'white' and there are some cortical cysts visible (white arrows to demonstrate whiteness of cortex). (**c**) Focal cystic disease. White arrow denotes eight separate cysts in a cluster. (**d**) Multicystic disease in a patient with *TSC1* mutation (**e**) Cortical cystic disease with cysts limited to cortex and columns of Bertin. White arrow denotes a single cyst. (**f**) Typical patient with both angiomyolipoma (white arrow) and stage 6 cortical cystic disease. (**g**) Same patient as in figure 'f' after 3 years of mTORC1 inhibition. Note angiomyolipoma shrinkage (white arrow) and significant improvement in cystic disease. (Figure (**b**) used with permission from [15])

TSC Microcystic Kidney Disease

The MRI findings of microcystic disease are subtle and are most often missed on ultrasound. The renal cortex exhibits increased water signal on T2 sequences, preceding discrete cortical cysts. While easily overlooked, this pattern of TSC-associated renal cystic disease is important because it is associated with a rapid decline in renal function, with patients developing chronic kidney disease stage 2 or 3 in their late teens or early 20s. Renal pyramids are spared so the urinary concentration capacity is preserved. There can be evidence of tubular proteinuria with increasing creatinine, but hypertension is not common until significant chronic kidney disease develops. This pattern does seem to be mTORC1 inhibitor responsive, though more research is needed.

TSC Focal Cystic Kidney Disease

Focal cystic disease manifests as a cluster of cysts and may be the result of a somatic mutation during branching morphogenesis, so that there is significant localized cystogenesis. The developmental timing can be in utero, resulting in an infant with an isolated site with profound cystic disease. The mutation may occur after a critical developmental period, and only become expressed after renal healing following acute kidney injury.

TSC Cortical Cystic Kidney Disease

A common distinct pattern of TSC cystic renal disease features cysts limited to the cortex and columns of Bertin. This cystic disease occurs early and the cysts initially exhibit a remarkably uniform size. This imaging pattern may suggest dilatation of tubular segments, or perhaps glomerulocystic disease.

TSC Multicystic Kidney Disease

The cysts in this pattern can be distributed throughout the cortical and medullary tissue and exhibit variable sizes with loss of corticomedullary differentiation. This pattern can be severe enough that it resembles the polycystic variety but is genetically distinct from the *TSC2/PKD1* contiguous gene syndrome.

Practical Approach to Surveillance and Treatment

Care of the TSC patient with renal involvement is best approached in a partnership with a TSC Center of Excellence. The newly diagnosed or suspected patient requires an abdominal MRI to assess for renal cysts and angiomyolipomata. MRI is required. Because of the high rate of fat poor lesions that have the same echotexture as normal kidney, making them virtually invisible to ultrasound. These patients also required renal function testing and blood pressure assessment. Patients with known disease require abdominal MRI every 1-to-3 years along with annual blood pressure and renal function testing. Asymptomatic, growing angiomyolipoma greater than three centimeters in diameter should be treated with an mTORC1 inhibitor, though a second-line approach for exophytic lesions could be sub-selective embolization or renal sparing surgery. Hemorrhaging angiomyolipomata should be treated with sub-selective embolization and the use of a corticosteroid protocol can eliminate the post-embolization syndrome.

Cell Biology of TSC Renal Disease

The basic science underpinning of TSC renal disease, in many ways, gave rise to pharmacotherapy. Understanding the cell biology of the disease will illuminate additional therapeutic avenues.

Angiomyolipomata

The cell of origin for the angiomyolipomata, categorized as a perivascular epithelial cell tumor (PEComa), is unclear. A neural crest cell of origin was suggested based on co-expression of melanocytic and smooth muscle cell markers [25, 40, 42]. However, re-expression of *TSC2* in an angiomyolipoma cell line altered the expression profile leading the investigators to doubt the neural crest cell origin and favor a lymphatic endothelium origin [78]. A dual knock-out of *Tsc2* and *Cdkn2a* in murine epithelial cells altered the cell expression to be somewhat similar to angiomyolipoma. However, *Cdkn2a* mutations are associated with melanoma, and this may confound the possible significance of the human melanoma black (HMB)-45 staining. The HMB-45 antibody is directed at premelanosome protein (PMEL)-17 and is useful in staining melanoma, angiomyolipoma, and the MITF transcription factor renal tumors. Mesenchymal stem cell-like cells have been identified in angiomyolipomata [75], and pericytes have been implicated as the cell of origin for angiomyolipomata [68]. This latter possibility is intriguing given that vascular aneurysms associated with TSC can arise in angiomyolipomata [74], the aorta [66], and the brain [7].

Angiomyolipomata belong to the PEComa family of tumors. This family is a unique and diverse group of tumors that exhibit both smooth muscle and melanocytic differentiation characteristics [59, 71]. Angiomyolipomas often have a triphasic appearance that includes thick-walled blood vessels, myoid-appearing perivascular cells, and lipid-distended cells resembling adipocytes. They can also resemble epithelioid cells and can have a very different mix of cells from tumor to tumor. There is an interesting interplay between the microphthalmia-associated transcription factor (MITF) family and the mTORC1 pathway, as is clearly suggested by the fact that angiomyolipomata express the melanotic marker PMEL (premelanosome protein, also known as SILV, gp100), the antigenic target for the diagnostic antibody HMB45 [76]. An interplay is also suggested by the hypopigmented macules that are part of the major diagnostic criteria [80]. This MITF/TFE transcription factor activity has also contributed to confusion between TSC-associated renal lesions and the much more aggressive renal cell carcinomas (RCCs) and PEComas associated with translocations involving TFE3 or TFEB [2].

Cystic Disease

The mTORC1 pathway is associated with primary cilia-associated cystogenesis. Unilateral nephrectomy in transgenic mice that underwent "adult-induced" cilia disruption exhibited significantly higher levels of mTORC1 activity in the remaining kidney compared to cilia-intact controls with increased cyst severity [6]. Although the polycystic disease-related proteins and primary cilia are mechanistically involved in polycystic kidney disease, they are not sufficient as the mediator. The loss of a polycystin protein or the primary cilia result in similar renal cystic disease phenotypes, but simultaneous inactivation of both the polycystin and cilia resulted in a decrease in PKD severity compared with polycystin-only knockout [52]. The polycystins must modulate an unidentified signaling pathway that requires intact cilia to function, implicating the primary cilia-extracellular vesicle axis. Extracellular vesicles (EVs) carry cargo including modulators of polycystic disease signaling, such as Hedgehog [67] and Wnt [65].

To understand the cystic disease in TSC better, a novel mouse model that inactivated the *Tsc2* gene in principal cells was generated by breeding a floxed *Tsc2* mouse to one containing Cre-recombinase driven by the aquaporin-2 promoter. The resulting mice have normal kidneys at birth but develop florid cystic disease by 19 weeks of age. Curiously, although the *Tsc2* gene was deleted in principal cells, the cysts were comprised of type A intercalated cells that contained an intact *Tsc2* gene [17]. Type A intercalated cells were also identified to be involved in human TSC-related cystic disease [17]. The mechanism for this cell nonautonomous trait may utilize EVs to reprogram cells [79], as has been suggested for another tumor predisposition syndrome. Chodankar et al. used a similar Cre-lox system to inactivate *Brca1* in mouse ovarian granulosa cells by using a truncated form of the *Fsh* receptor promoter to drive Cre recombinase. The authors demonstrated that inactivation of the *Brca1* gene in granulosa cells led to the development of cystic tumors with genetically intact *Brca1* genes in the ovaries and uterine horns. They posited that the loss of *Brca1* may influence tumor development indirectly through some form of effector secreted by granulosa cells [22].

In mouse models studied, there seems to be significant elevation of cyst mTORC1 activity (phospho-S6 expression), but a very low percentage of cells exhibiting loss of Tsc expression [3, 60, 81]. The somatic mutation (second hit) dogma of TSC renal disease is difficult to reconcile with the early investigations that failed to find loss of heterozygosity in a majority of cysts, indicating that the majority of renal cysts maintain their *Tsc* locus integrity [60, 72]. This low percentage of cysts with loss of heterozygosity is similar to human TSC renal cystic disease, because human cysts also continue to express tuberin and hamartin. In contrast, the mechanism for angiomyolipomata shows an inactivating mutation and loss of heterozygosity resulting in the loss of tuberin staining [20]. Such a low percentage of loss of heterozygosity is also seen in PKD1 associated autosomal dominant polycystic kidney disease, suggesting that such cystic disease may represent a unique disease mechanism [5, 21].

Oncocytoma and Renal Cell Carcinoma

Patients with TSC are also reported to have renal oncocytomas and renal cell carcinomas [8]. Renal oncocytomas histologically contain nests and tubular structures lined by cells with eosinophilic, granular cytoplasm [73]. Histologic diagnosis is challenging when lesion patterns are complex. For example, a solid lesion with highly compact nested architecture or with small papillary structures protruding into cystic spaces is similar to the eosinophilic variant of papillary renal cell carcinoma. Oncocytomas contain edematous myxoid or hyalinized stroma with some areas with nests and tubular structures. Clear cytoplasm may be focally present, and cells in these lesions have round nuclei and can contain areas of degenerative cytologic atypia. These features result in patches of tumor cells containing large nuclei, irregular nuclear contours, and smudged chromatin [70]. This lesion is almost always described as benign. Renal cell carcinoma is also described in patients with TSC [18], but the frequency for TSC is likely much lower and inflated estimates of 2% are difficult to substantiate because the data are rarely in collected series [41]. In the largest retrospective study of 2216 subjects, renal malignancy was reported in 1.1% of subjects [48]. Other inherited renal cancer predisposition syndromes have a more elevated risk, such as Birt-Hogg-Dubé with an estimated frequency for renal malignancy of about 25% [53].

Abstract

Nephronophthisis (NPHP) is an autosomal recessive cystic kidney disease that constitutes one of the most frequent genetic causes for end-stage kidney disease (ESKD) in the first three decades of life [1–4]. Three clinical forms of NPHP have been distinguished by age of onset of ESKD: infantile [5, 6], juvenile [7], and adolescent NPHP [8], which manifest with ESKD at median ages of 1 year, 13 years, and 19 years, respectively. Initial symptoms are relatively mild with the exception of infantile NPHP type 2. They consist of polyuria, polydipsia with regular fluid intake at nighttime, secondary enuresis, anemia, and growth retardation [8]. A slightly raised serum creatinine is noted at an average age of 9 years, before ESKD invariably develops within a few years (Fig. 1a). Renal ultrasound reveals increased

echogenicity (Fig. 1b). Beyond the age of 9 years, cysts appear at the corticomedullary junction within the kidneys of normal or slightly reduced size (Fig. 1b) [9]. Renal histology reveals a characteristic triad of tubular basement membrane disruption, tubulointerstitial nephropathy, and cysts (Fig. 1c) [10, 11]. In nephronophthisis, cysts arise from the corticomedullary junction of the kidneys (Fig. 1b). Because kidney size is normal or slightly reduced, cysts seem to develop ex vacuo through loss of normal tissue. This is in contrast to polycystic kidney disease, where cysts are distributed evenly and lead to gross enlargement of the kidneys [12]. NPHP is part of a broad spectrum of renal cystic/degenerative diseases that often include extrarenal manifestations. Over 90 recessive single-gene causes have been identified. Because the related gene products localize to primary cilia and centrosomes, the term “NPHP-related ciliopathies (NPHP-RC)” is now used for these disorders.

Natural History of Nephronophthisis and Related Ciliopathies

Nephronophthisis (NPHP) is an autosomal recessive cystic kidney disease that constitutes one of the most frequent genetic causes for end-stage kidney disease (ESKD) in the first three decades of life [1–4]. Three clinical forms of NPHP have been distinguished by age of onset of ESKD: infantile [5, 6], juvenile [7], and adolescent NPHP [8], which manifest with ESKD at median ages of 1 year, 13 years, and 19 years, respectively. Initial symptoms are relatively mild with the exception of infantile NPHP type 2. They consist of polyuria, polydipsia with regular fluid intake at nighttime, secondary enuresis, anemia, and growth retardation [8]. A slightly raised serum creatinine is noted at an average age of 9 years, before ESKD invariably develops within a few years (Fig. 1). Renal ultrasound reveals increased echogenicity (Fig. 1b). Beyond the age of 9 years, cysts appear at the corticomedullary junction within the kidneys of normal or slightly reduced size (Fig. 1b) [9]. Renal histology reveals a characteristic triad of tubular basement membrane disruption, tubulointerstitial nephropathy, and cysts (Fig. 1c) [10, 11]. In nephronophthisis, cysts arise from the corticomedullary junction of the kidneys (Fig. 1b). Because kidney size is normal or slightly reduced, cysts seem to develop ex vacuo through loss of normal tissue. This is in contrast to polycystic kidney disease, where cysts are distributed evenly and lead to gross enlargement of the kidneys [12]. NPHP is part of a broad spectrum of renal cystic/degenerative diseases that often include extrarenal manifestations. Over 90 recessive single-gene causes have been identified. Because the related gene products localize to primary cilia and centrosomes, the term “NPHP-related ciliopathies (NPHP-RC)” is now used for these disorders.

NPHP-RC are inherited in an autosomal recessive mode and include NPHP-RC variants with extrarenal manifestations [1, 12, 14], which are present in more than 20% of patients with NPHP. Extrarenal involvement primarily includes retinal degeneration (Senior-Loken syndrome) [15, 16], cerebellar vermis aplasia (Joubert syndrome) [17, 18], liver fibrosis [19, 20], cone-shaped epiphyses [21, 22], and thoracic dystrophy (Jeune syndrome) [22]. The most severe syndromic manifestation of ciliopathies, Meckel-Gruber syndrome, is characterized by severe dysplastic multi-organ defects and embryonic lethality [23]. Extrarenal manifestations of NPHP-RC will be discussed below in light of the cilia/centrosome theory. NPHP has previously been grouped together with the clinical entity of

medullary cystic kidney disease (MCKD) [7, 10], due to similarities of clinical and pathologic features [24]. Both NPHP and MCKD feature corticomedullary cysts in the kidneys of normal or slightly reduced size. However, MCKD is clearly distinct from NPHP regarding multiple aspects: [1] MCKD follows autosomal dominant inheritance, [2] ESKD occurs in the fourth decade or later, and, [3] in MCKD, there is no extrarenal involvement other than hyperuricemia and gout (see ▶ Chap. 53, "Autosomal Dominant Tubulointerstitial Kidney Disease").

Nephronophthisis and related ciliopathies seem to be distributed evenly among males and females. Nephronophthisis has been reported from virtually all regions of the world [25] with an incidence of nine patients/8.3 million [26] in the United States or 1 in 50,000–80,000 live births in Canada [27] and Finland [28], respectively. The condition constitutes one of the most frequent genetic causes for ESKD in the first three decades of life and is a major cause of ESKD in children, accounting for ~ 5% of pediatric patients requiring renal replacement therapy in Europe [29]. In the North American pediatric ESKD population, pooled data indicate a prevalence of less than 5% [30]. MCKD appears to be somewhat less frequent.

NPHP was first described by Smith and Graham in 1945 [2] and by Fanconi et al. [3], who introduced the term "familial juvenile nephronophthisis." In NPHP, the earliest presenting symptoms are polyuria, polydipsia, decreased urinary concentrating ability, and secondary enuresis.

They occur in over 80% of cases [25] and start at around 6 years of age. In these early stages, regular fluid intake at nighttime is a characteristic feature of the patients' history. Anemia and growth retardation develop later in the course of the disease [31]. Due to the mild nature of symptoms and the lack of edema, hypertension, and urinary tract infections, there is often a delay in the diagnosis of NPHP. This may cause a risk of sudden death from fluid and electrolyte imbalances. Disease recurrence has never been reported in the kidneys transplanted to NPHP patients [32]. The early genes identified to cause NPHP, if mutated, were detected by positional cloning. Subsequently, advances in next-generation sequencing and bioinformatics have facilitated the identification of more than 90 different genes mutated in NPHP and related ciliopathies. This has made definite molecular genetic diagnostics possible (www.renalgenes.org). Mode of inheritance in NPHP-RC is strictly recessive, and as expected in a recessive disease, phenotypic penetrance seems to be 100%. However, there are allelic differences regarding disease severity and expected frequencies of distinct organ manifestations. Genes that may also cause non-syndromic NPHP have been numbered as *NPHP* genes *1–20* (www.omim.org, OMIM® Copyright® 1966–2020 Johns Hopkins University). Homozygous deletions in the *NPHP1* gene account for approximately 25% of NPHP cases [33], whereas mutations in any of the other NPHP-RC genes are each relatively rare.

In NPHP, chronic kidney disease develops before the age of 25 years [8, 34, 35]. Infantile NPHP, which is caused by mutations in *NPHP2/inversin*, leads to ESKD between birth and 3 years of age [6, 35]. In a study conducted in 46 children with juvenile NPHP type 1 caused by mutations of the *NPHP1* gene, a serum creatinine of 6 mg/dl was reached at a median age of 13 years of age (range 4–20 years) (Fig. 1a) [7, 13]. The median time lapse between a serum creatinine of 2 and 4 mg/dl was 32 months and between 4 and 6 mg/dl 10 months (Fig. 1a) [36]. Similarly, the median age of ESKD in patients with mutations in the *NPHP5* gene was 13 years [37]. In patients with adolescent NPHP due to mutations in the *NPHP3* gene, ESKD developed by 19 years of age [8]. If renal failure has not developed by the age of 25 years, the diagnosis of recessive NPHP should be questioned and autosomal dominant MCKD/tubulointerstitial kidney disease (ADTKD) should be considered as a differential diagnosis. In MCKD/ADTKD, ESKD occurs later in life. MCKD types 1 and 2 show a median onset of ESKD at 62 years [38] and 32 years [39], respectively.

Pathology and Histopathology

Renal histopathology is very similar in NPHP and classic MCKD and has been described comprehensively in 27 patients with NPHP by Waldherr and associates [10, 11] (Fig. 1c). Kidney size is normal or moderately reduced. There is always bilateral renal involvement. Macroscopically, the kidney surface has a finely granular appearance, most likely due to the protrusion of dilated cortical collecting ducts. There are between 5 and approximately 50 cysts of 1–15 mm in diameter, located preferentially at the corticomedullary border. The cysts arise primarily from the distal convoluted and medullary collecting tubules as shown by microdissection [40] but may also appear in the papilla. Cysts are observed only in about 70% of autopsy cases and seem to arise late in the course of the disease [41]. Therefore, the presence of cysts is not a prerequisite for diagnosis. No cysts are present in organs other than the kidney. The histologic changes of NPHP are characteristic but not specific for the disease and seem to develop only postnatally. Typically, there is pronounced thickening and multilayering of the tubular basement membrane (TBM), which represents the most characteristic histologic feature of NPHP (Fig. 1c). By light microscopy, there appears to be a specific sequence of events: TBM disruption is followed by lymphocytic and histiocytic peritubular infiltration. Subsequently, atrophic or dilated and tortuous tubules develop predominantly at the corticomedullary junction. In advanced stages, the picture merges into a diffuse sclerosing tubulointerstitial nephropathy. TBM changes and cyst formation are most prominent in distal tubules, where cysts are lined with a single layer of cuboidal or flattened epithelium [42–45]. Glomeruli demonstrate periglomerular fibrosis with splitting and thickening of Bowman's capsule. Glomerular obsolescence is only present in nephrons that have been destroyed by tubular alterations. On transmission electron microscopy, the tubular basement membrane shows thickening, splitting, attenuation, and granular disintegration without clear stages of transition [11]. A marked increase of microfilaments is seen at the base of the tubular epithelial cells.

Molecular Genetics and Disease Mechanisms

A positional cloning approach was used to gain insight into the pathogenesis of NPHP. This has revealed recessive mutations in nine different novel genes as causing NPHP. These are *NPHP1* [34, 46], *NPHP2/inversin* [6], *NPHP3* [47], *NPHP4* [48, 49], *NPHP5* [37], *NPHP6/CEP290* [50, 51], *NPHP7/GLIS2* [52], *NPHP8/RPGRIP1L* [53–55], and *NPHP9/NEK8* [56], defining NPHP types 1–9, respectively (Table 1).

Subsequently, genetic mapping, whole-exome sequencing (WES), and recently whole-genome sequencing have accelerated gene identification and led to the identification of 20 genes that may cause isolated NPHP, known to date. These define NPHP types 1–20. Additionally, more than 90 causative genes within the group of nephronophthisis-related ciliopathies (NPHP-RC) have been identified as causing syndromic ciliopathies that may include NPHP or related renal phenotypes (Table 1). All NPHP-RC genes are monogenic recessive (Mendelian) genes, implying that biallelic mutations in each single gene are in itself sufficient to cause NPHP by about 20 years of age, indicating that their gene products are necessary for normal kidney function. Gene identification has thereby generated new insights into normal function of tubular kidney epithelia and into disease mechanisms of NPHP and has revealed that molecular pathogenesis is related to signaling mechanisms of primary cilia, centrosomes, and planar cell polarity [1, 6, 57, 58] (see below and Fig. 2).

Identification of over 90 NPHP-RC-causing genes revealed multiple features as characteristic of NPHP-RC (Hildebrandt, 2011) (Table 1):

- NPHP-RC involves multiple organs (pleiotropy), depending on the mutated gene and allele.
- NPHP-RC proteins participate in protein complexes ("NPHPomes"), which dynamically localize to cilia, centrosomes, or the mitotic spindles in a cell cycle-dependent manner [20, 59].
- There is strong evolutionary conservation of NPHP proteins.
- Animal models (mice, zebrafish, *C. elegans*) are faithful disease models for NPHP-RC.
- NPHP-RC proteins participate in diverse signaling pathways (Wnt, Shh, hippo, mTOR, DNA damage response signaling, and cell cycle regulation) with the centrosome as an integrator.

Gene identification has made definite molecular genetic diagnostics possible (www.renalgenes.org) for approximately 50–70% of cases, depending on the composition of the cohort. Familial occurrence, parental consanguinity, early onset, and syndromic phenotypes are factors that suggest monogenic disease causation and increase the likelihood for positive results in genetic testing [60, 61]. Due to the large number of NPHP-RC genes and their overlapping clinical phenotypes, whole exome sequencing is the preferred technique for genetic diagnostics [62, 63]. However, gene panels by high-throughput multiplex PCR have also been used successfully [64]. Homozygous deletions in the *NPHP1* gene account for approximately 21% of all NPHP cases, thus representing by far the most common cause of NPHP. In comparison, mutations in all other genes are very rare, some occurring in less than ten families worldwide. The phenomenon of different gene mutations that all result in a similar phenotype is defined as genetic heterogeneity. Presently, the causative gene remains undetected in about 30% of cases, indicating that additional novel NPHP genes are yet to be identified. Some reports have suggested oligogenic inheritance in NPHP [65] and related ciliopathies [66–68], describing that more than one recessive gene may be mutated in some NPHP patients.

Table 1 Single-gene[a] causes of nephronophthisis-related ciliopathies (NPHP-RC). The table lists genes, protein complexes[b] ("NPHPomes"), OMIM[c] number for NPHP type, signaling mechanisms involved in the pathogenesis, organ involvement, syndromic spectrum (Joubert, Meckel, or Jeune syndromes), and animal models of NPHP-RC

Fig. 2 Schematic structure of primary cilia and intraflagellar transport. The cilium is a hairlike structure that extends from the cell surface to the extracellular space. Virtually all vertebrate cell types can produce cilia. Cilia consist of a microtubule-based axoneme covered by a specialized plasma membrane. The axoneme has nine peripheral microtubule doublets. There may be two central microtubules (9 + 2 vs. 9 + 0 axoneme). 9 + 2 cilia usually have dynein arms that link the microtubule doublets and are motile, while most 9 + 0 cilia lack dynein arms and are nonmotile ("primary cilia"). The ciliary axoneme is anchored in the basal body, a microtubule-organizing center derived from the mother centriole. The transition zone at the junction of the basal body acts as a filter for any molecules that pass into or out of the cilium. Nephrocystin-1 is localized at the transition zone of epithelial cells [84]. During ciliogenesis, cilia elongate from the basal body by the addition of new axonemal subunits to the distal tip, the plus end of the microtubules. Axonemal and membrane components are transported in macromolecular particles (complexes A and B) by so-called intraflagellar transport (IFT) along the axonemal doublet microtubules [85]. Anterograde transport toward the tip is driven by heterotrimeric kinesin-2, which contains motor subunits Kif3a and Kif3b and a non-motor subunit. Mutations of *Kif3a* cause renal cysts and cerebellar vermis aplasia in mice [86]. Retrograde transport back to the cell body occurs via the motor protein cytoplasmic dynein 1b [87]. (Modified from Bisgrove and Yost, 2006 [88])

In the following, central aspects of the pathogenesis of NPHP will be discussed in the context of the discovery of NPHP genes 1–20 (Table 1). The structure and function of primary cilia and basal bodies are delineated in Fig. 2.

NPHP1

In juvenile nephronophthisis (NPHP type 1), a gene locus was mapped to chromosome 2q12.3 [69]. This locus was further refined [70–74], and the gene *NPHP1* responsible for NPHP type 1 was identified by positional cloning [34, 46]. About 85% of patients with NPHP type 1 carry large homozygous deletions of the *NPHP1* gene [75, 76]. Spontaneously occurring deletions of the *NPHP1* locus [77] as well as specific loss-of-function point mutations of *NPHP1* have been identified [34, 78]. In a subset of patients with large deletions in *NPHP1*, there is an association with oculomotor apraxia type Cogan [76]. Another subset shows an association with retinitis pigmentosa [78]. *NPHP1* encodes nephrocystin-1, a protein that interacts with components of cell-cell and cell-matrix signaling, including p130Cas [79], focal adhesion kinase 2 [79], tensin, and filamins A and B [80]. It is located at adherens junctions and focal adhesions of renal epithelial cells [81], which are involved in cell-cell and cell-basement membrane contacts, respectively (Fig. 3). Nephrocystin-1 also interacts with proteins encoded by other NPHP genes such as nephrocystin-2/inversin [6], nephrocystin-3 [47], and nephrocystin-4 [48, 49]. Nephrocystin-1 and nephrocystin-4 interact and colocalize with microtubules in primary cilia and at mitotic spindle poles, suggesting that nephrocystin may also play a role in cell division [82]. Knockdown of *NPHP1* resulted not only in defects of cilia formation but also in impaired assembly of tight junctions and epithelial cell polarity [83]. These data indicate that loss of cell orientation and alterations in cell division due to NPHP gene mutations may be two mechanisms that contribute to cyst formation in affected kidneys (Fig. 4).

NPHP2/Inversin

Infantile nephronophthisis (NPHP type 2) was recognized as a distinct disease entity, in which end-stage renal failure occurs within the first 3 years of live [5, 89] (Table 1). Macroscopically, NPHP type 2 differs from other forms of NPHP by the presence of enlarged kidneys and cortical microcysts and by the absence of medullary cysts. Histologically, there is no disruption of tubular basement membranes. Mutations of *NPHP2/INVS* were identified as the cause of infantile NPHP (type 2) with and without *situs inversus* [6] by positional cloning [35] and using candidate gene data [90, 91]. The renal cystic changes of infantile nephronophthisis combine clinical features of NPHP and of PKD [5]. The gene products nephrocystin-1 (NPHP1) and NPHP2/inversin interact with β-tubulin, which constitutes the microtubule axoneme of primary cilia (Fig. 2), and they are localized at primary cilia of renal tubular cells (Fig. 3) [6]. These findings supported a unifying theory of renal cystogenesis [1, 57, 92, 93], which states that proteins mutated in renal cystic disease (“cystoproteins”) in humans, mice, or zebrafish localize to primary cilia, basal bodies, or centrosomes in a cell cycle-dependent way [6, 57]. Basal bodies are the foundations from which cilia are assembled. Once mitosis and cell division are completed, basal bodies derive from the *mother* centriole that had previously organized the mitotic spindle in cell division. When cilia are formed from the basal body, the *daughter* centriole is placed on the side of the nucleus opposite to the basal body, thus specifying cell polarity (Fig. 3). Primary cilia are highly conserved structures that sense extracellular cues in a broad spectrum of epithelial tissues. There is a wide range of cues that can be received by specific ciliary receptors, including photosensation, mechanosensation, osmosensation, and olfactory sensation. In general, it seems that the pathogenesis of ciliopathies is based on an inability of epithelial cells to sense or process extracellular cues [94]. Similar to other cystoproteins, inversin was shown to localize to different subcellular locations in a cell cycle-dependent manner. Specifically, it is found at the mitotic spindle in mitosis; at the midbody in cytokinesis; and in cilia, their basal body, or centrosomes in interphase (Fig. 3). All of these

Fig. 3 Subcellular localization of nephrocystins to primary cilia, basal bodies, the mitotic spindle, focal adhesions, and adherens junctions, as well as functional interaction with other proteins mutated in renal "ciliopathies." "Cystoproteins" are proteins of genes mutated in cystic kidney diseases of humans, mice, or zebrafish. Depending on cell cycle stage, cystoproteins are localized at different subcellular organelles (shown in gray) [50, 96] including primary cilia, basal bodies, the endoplasmic reticulum, the mitotic spindle, centrosomes, adherens junctions, or focal adhesions. Arrows in the primary cilium indicate the direction of anterograde transport along the microtubule system mediated by kinesin-2 and retrograde transport by cytoplasmic dynein 1b. Most nephrocystins (blue) are located at cilia, the basal body, and centrosomes in a cell cycle-dependent manner. NPHP1 is also at the transition zone, focal adhesions, and adherens junctions. NPHP2/inversin and NPHP7/Glis2 can enter the nucleus and act as transcription factors. Sensory cilia perceive and process external signals, and "cystoproteins" are involved in signaling mechanisms downstream of ciliary signal recognition (pink). Downstream of cilia, Wnt signaling plays a role in planar cell polarity, which is mediated partially through orientation of centrosomes and the mitotic spindle poles. Cilia and ciliary proteins are functionally connected to the hedgehog and hippo signaling pathway. DNA damage response signaling (DDR), disrupted in some ciliopathies, may result in apoptosis and tissue degeneration. "Cystoproteins" with centrosomal/mitotic spindle localization may interfere with cell cycle regulation. Cilia-dependent mechanisms of planar cell polarity seem to be central to the pathogenesis of the ciliopathies, the most prominent of which is listed on the right. *Wnt* the Wnt signaling pathway, *Shh* the sonic hedgehog signaling pathway

organelles are involved in regulation of planar cell polarity or the cell cycle (see below). In this context, a major breakthrough was made for the understanding of the pathogenesis of renal cystic diseases when Simons et al. demonstrated a role of inversin/NPHP2 in signaling mechanisms of planar cell polarity, in particular Wnt signaling, necessary to maintain normal tubular development and morphology [95]. The proposed link between cell cycle defects, disruption of apical-basolateral polarity, and renal cyst formation is schematically summarized in Fig. 4 [58].

NPHP3

In a large Venezuelan kindred, we used positional cloning to identify missense mutations in *NPHP3* as responsible for adolescent nephronophthisis (Table 1) [8, 47]. Analogously, it was demonstrated that mutations in the mouse ortholog *Nphp3* are responsible for the renal cystic mouse mutant *pcy* [47], which was demonstrated to be responsive to treatment with a vasopressin receptor antagonist [97]. Missense mutations are mutations in which one single amino acid of the encoded protein is replaced by another amino

Non-directional cell division?
Disrupted planar orientation?

Fig. 4 Defects of cystoproteins lead to disruption of planar cell polarity and thereby to renal cysts through malorientation of the centrosome or the mitotic spindle. Correct orientation of the mitotic spindle and centrosomes with respect to the longitudinal axis of the tubule is critical for proper planar cell polarity (i.e., the orientation of an epithelial cell layer in three-dimensional space). Noncanonical Wnt signaling is involved in regulation of planar cell polarity during renal tubular morphogenesis, when in rodents 2 weeks *post-partum* the tubules still elongate. The structure that would result from disruption of this longitudinal orientation is a dilated tubule or cyst. (Adapted from [58])

acid. In contrast, truncating mutations introduce a premature stop codon and result in a shortened protein that is frequently degraded by mechanisms of nonsense-mediated decay. Therefore, truncating mutations are more likely to convey complete loss of function of the respective protein, while missense mutations may lead to partial residual protein function. In mice, complete loss of NPHP3 function results in *situs inversus*, congenital heart defects, and embryonic lethality [98]. Similarly, truncating mutations of *NPHP3* in humans can cause a clinical pattern that resembles Meckel syndrome. The phenotype of these patients included *situs inversus*, polydactyly, central nervous system malformations, structural heart defects, preauricular fistulas, and congenital anomalies of the kidney and urinary tract (CAKUT) [98]. A correlation between the “severity” of the underlying mutation and the resulting clinical phenotype has been observed for many NPHP genes. The notion that different mutations in the same gene can cause variable phenotypes is described as multiple allelism or phenotypic heterogeneity. Interestingly, truncating mutations of *NPHP3* give rise to developmental defects of the kidney, while patients with missense mutations have apparently normal kidneys at birth and only later in life develop degenerative renal disease. Thus, for NPHP-RC genes, there appears to be a phenotypic continuum from developmental defects to degenerative diseases of various organs.

NPHP4

Mutations in the gene *NPHP4* were identified by homozygosity mapping and total genome search for linkage [48, 49, 99] (Table 1). Nephrocystin-4, like inversin, localizes to primary cilia, basal bodies, centrosomes, and the cortical actin cytoskeleton [82] (Fig. 3).

NPHP5

Recessive mutations in the gene *NPHP5* were identified as mutated in nephronophthisis type 5 [37]. All mutations detected resulted in truncations of the encoded protein nephrocystin-5, and all patients had an association with early-onset retinal degeneration. Thus, *NPHP5* represents the gene mutated in the classical early-onset form of Senior-Loken syndrome (SLS) (Table 1). Nephrocystin-5 contains an IQ domain, which directly interacts with calmodulin [37], and is in a complex with the retinitis pigmentosa GTPase regulator (RPGR), which when defective causes X-linked retinitis pigmentosa. Both nephrocystin-5 and RPGR are localized in connecting cilia of photoreceptors and in primary cilia of renal epithelial cells [37]. The fact that connecting cilia of photoreceptors are the structural equivalents of primary cilia of renal epithelial cells rendered an explanation for retinal involvement in the retinal-renal syndrome Senior-Loken syndrome.

NPHP6/CEP290

Recessive truncating mutations in the gene *NPHP6/CEP290* were identified as the cause of NPHP type 6 and Joubert syndrome type 5 by positional cloning [50]. Its gene product nephrocystin-6/CEP290 is part of the centrosomal proteome [100] (Table 1). Similar to NPHP2/inversin and NPHP4, NPHP6/CEP290 is expressed in centrosomes and the mitotic spindle in a cell cycle-dependent manner. Abrogation of *nphp6* function in zebrafish caused planar cell polarity defects and recapitulated the human phenotype of NPHP type 6, including renal cysts, retinal degeneration, and cerebellar defects [50]. Nephrocystin-6 modulates the activity of ATF4/CREB2, a transcription factor that may be implicated in cAMP-dependent renal cyst formation [101]. Interestingly, a 300-amino acid in-frame deletion of *Nphp6/Cep290* caused retinal degeneration only, without renal or cerebellar involvement in the *rds16* mouse model [102] (Table 1). This is in accordance with the recent finding that hypomorphic mutations of *NPHP6/CEP290* represent the most frequent cause of Leber's congenital amaurosis [103]. Mutations in *NPHP6/CEP290* have been confirmed as causing Joubert syndrome (JBTS, see below) with and without renal involvement [51]. Truncating mutations in *NPHP6* were shown to cause Meckel syndrome [104]. This is another example of multiple allelism in NPHP-RC.

Correct orientation of the mitotic spindle and centrosomes with respect to the longitudinal axis of the renal tubule is critical for proper apical-basolateral polarity (Fig. 4). Noncanonical Wnt signaling is involved in these processes in renal tubular morphogenesis, when in rodents renal tubules still elongate postnatally. The structure resulting from disruption of the longitudinal growth would be a dilated tubule or cyst (Fig. 4). Additional evidence for a role of planar cell polarity in renal cystic diseases was generated by measuring orientation of the mitotic spindle through 3-D imaging of renal tubules [105]. Comparison of the distribution of the mitotic angles in wild-type animals and rodent cystic kidney disease models revealed that mitotic angles of two rodent models of cystic kidneys, the HNF1β-deficient mouse model and the *pck* rat model, differed from wild-type littermates [105].

NPHP7/GLIS2

Mutations in the *NPHP7/GLIS2* gene, encoding the transcription factor Gli-similar protein 2 (Fig. 3), were discovered as the cause of NPHP type 7 [52]. In analogy, *Glis2* mutant mice showed severe renal atrophy and fibrosis resembling human nephronophthisis [52] (Table 1). Differential gene expression studies on *Glis2* mutant kidneys demonstrated that genes promoting epithelial-to-mesenchymal transition and fibrosis are upregulated in the absence of *Glis2* [52]. There was also prominent apoptosis present in distal tubular segments of the kidney, which might provide an explanation why, in contrast to PKD, kidney size is reduced in NPHP. As GLIS2 is related to the GLI transcription factor, these findings implicated the hedgehog signaling pathway in the pathogenesis of cystic kidney diseases [106]. Hedgehog is a signaling pathway that controls cell determination and tissue patterning during embryogenesis. Subsequently identified NPHP genes, in particular those associated with skeletal phenotypes (see below), further supported a role of hedgehog signaling in the pathogenesis of NPHP-RC.

NPHP8/RPGRIP1L

Missense and truncating mutations in the *NPHP8/RPGRIP1L* gene were shown to cause Joubert syndrome and Meckel syndrome, respectively [54] (Table 1). RPGRIP1L colocalized with the protein products of *NPHP6* and *NPHP4* at the basal body and centrosomes [54] (Fig. 3). While two truncating mutations caused Meckel syndrome, missense mutations were seen in patients with Joubert syndrome [54, 55]. These findings confirmed that there is a continuum for the phenotypic abnormalities found in Meckel syndrome, in Joubert syndrome, and in nephronophthisis on the basis of distinct mutations in the identical genes (multiple allelism).

NPHP9/NEK8

Three different highly conserved amino acid changes (missense mutations) were identified in the gene *NEK8* (never in mitosis kinase 8) as causing NPHP type 9 [56] (Table 1). One of the mutations identified in human patients affected the same RCC1 domain, in which the missense mutation causing the renal cystic mouse model *jck* is also positioned [107, 108]. The notion that mutations in *NEK8* cause nephronophthisis was further supported by cell culture experiments: Upon expression in medullary collecting duct cells, all three mutant forms of *NEK8* showed defects in subcellular localization; specifically, ciliary and centrosomal localization of mutant NEK8 was disrupted [56]. As NEK8 plays a major role in cell cycle regulation, these data provided further evidence for a functional link between renal cyst formation and cell cycle dysregulation. At the same time, it further supported the dual role of ciliary/centrosomal proteins as cell cycle regulators. In this context, it is interesting that two mouse models of polycystic kidney disease (*jck* and *cpk*) can be efficiently treated with the cyclin-dependent kinase inhibitor roscovitine [109].

ZNF423 and CEP164

Mutations in zinc finger protein 423 (*ZNF423*) and centrosomal protein 164 (*CEP164*) were identified as causing NPHP types 14 and 15, respectively [110]. These findings implicated the ataxia telangiectasia mutated (ATM) branch of DNA damage response (DDR) signaling in the pathogenesis of NPHP-RC [111]. A role of DDR was then confirmed for the fanconi anemia 1 (FAN1) branch of DDR in NPHP-RC like disease “karyomegalic interstitial nephritis” [112] and for the ataxia telangiectasia and Rad3-related (ATR) branch of DDR by the description of DDR defects in a mouse model of *Nek8/Nphp9* loss of function [113]. Genomic integrity in mammalian cells is closely monitored by the DDR signaling network, which, upon detection of DNA damage, induces cell cycle arrest to facilitate DNA repair. In conditions of profound DNA damage, when repair fails, apoptosis is initiated to eliminate defective cells and maintain genomic integrity. Experimental studies in cell culture, zebrafish, and mice demonstrated that in addition to their canonical function in cilia and centrosomes, some NPHP proteins carry additional functions in DDR regulation [110, 114, 115]. Dysregulation of DDR signaling in patients with NPHP-causing mutations may contribute to the development of renal fibrosis by inducing apoptosis and epithelial-to-mesenchymal transition with concomitant fibrosis in renal epithelial cells [110, 114, 115] (Fig. 5). Centrosomal proteins, such as CEP164 and CEP290, thus have multiple cellular functions, i.e., in cilia, cell cycle regulation, and DDR signaling that may collectively contribute to NPHP pathogenesis (Fig. 3).

WDR19/NPHP13, IFT172/NPHP17, and Other Genes Encoding Intraflagellar Transport (IFT) Proteins

Fig. 5 Primary cilia play a critical role in numerous signaling pathways, among them DNA damage response (DDR) signaling. In events of DNA damage, several centrosomal proteins translocate to nuclear foci where they colocalize with the TIP60 complex. A number of ciliopathy proteins harbor this dual function and modulate different branches of the DDR signaling network. In ciliopathies, dysregulation of DDR signaling in renal epithelial cells may induce apoptosis and concomitant tissue fibrosis, thereby driving the degenerative renal phenotype of NPHP, which significantly differs from PKD with respect to pathogenesis and histology. Light red defines essential proteins of the DDR pathway; dark red defines NPHP proteins that are functionally connected to DDR signaling. Abbreviations: ATR, ataxia telangiectasia and Rad3 related; ATM, ataxia telangiectasia mutated; FAN1, fanconi anemia 1; ATR/ATM/FAN1, different branches of DDR signaling; γH2Ax, gamma histone-H2AX

in patients with cranioectodermal dysplasia, retinitis pigmentosa, and renal cysts [116, 117]. Subsequently, barcoded multiplex PCR-based screening in a large international cohort reported *WDR19* mutations in patients with NPHP with/without retinal degeneration [64]. Mutations in

IFT172 were identified as causing NPHP type 17 combined with short-rib polydactyly [22]. IFT proteins form two distinct multiprotein complexes, ITFA and IFTB, required for anterograde and retrograde transport along the ciliary axoneme, respectively (Fig. 2). Both IFT complexes are highly conserved across evolution from green algae to humans and function as adaptors between ciliary motor proteins, i.e., kinesins and dyneins, and their respective cargo. As cilia are sensory organelles required for sensing and processing of extracellular cues, ciliary transport of messenger molecules directed for the nucleus is essential for rapid signal transduction. Impairment of ciliary transport proteins due to mutations will presumably cause a block in a cell's ability to respond to external cues, thereby resulting in tissue dysplasia or degeneration, depending on the severity of the defect. Additionally, cilia do not contain any intrinsic machinery for protein biosynthesis, which might explain why genetic inactivation of IFT proteins in mice disrupts ciliogenesis (formation of cilia) [86]. Mouse models with lack of cilia due to IFT disruption developed renal cysts and thereby supported the proposed link between ciliary defects and renal cyst formation. Interestingly, patients with mutations in genes encoding IFT proteins mostly displayed skeletal ciliopathies, such as Jeune's asphyxiating thoracic dystrophy (JATD), short-rib polydactyly syndrome, Mainzer-Saldino syndrome, or Sensenbrenner syndrome (cranioectodermal dysplasia) (see below). This phenomenon is thought to result from disruption in the hedgehog signaling pathway [22, 118] (Fig. 3), a pathway that is essential for skeletal development. Additional organ manifestations in these patients varied depending on the mutated gene and the specific allele and included NPHP, retinal degeneration, liver fibrosis, and cerebellar vermis hypoplasia [22, 64, 117, 118].

ANKS6/NPHP16

Mutations in *ANKS6* were found in patients with NPHP type 16 and mostly infantile onset of renal cystic disease combined with congenital heart defects and congenital liver fibrosis [119], suggesting that ANKS6 was involved in renal, cardiac, and hepatic morphogenesis. ANKS6 was shown to localize to the proximal compartment of the ciliary axoneme, where it forms a multiprotein complex with three other "NPHP proteins," namely, NPHP3, INVS, and NEK8 [119] (Table 1). A knockout mouse model of *Anks6* displayed abnormal cilia as well defects in bile duct formation and cholangiocyte differentiation, which the authors found were related to disruptions in the hippo signaling pathway [120]. This study thereby defined another signaling network essential to organ development, which is functionally connected to cilia. A recent study furthermore detected RNA-binding properties in the ankyrin repeat domain of ANKS6 as well as inversin (NPHP2) and demonstrated that both proteins can translocate into RNA-containing granules in response to cellular stress. These findings support the observation that certain NPHP proteins act as intracellular sensors for conditions of genomic stress [121].

CEP83/NPHP18

Patients with homozygous or compound heterozygous mutations in *CEP83* had early onset of NPHP with rapid progression to ESKD. Additionally, some patients had hydrocephalus and/or variable degrees of intellectual disability [122]. *CEP83*, like *CEP164*, encodes a centrosomal protein that is an essential component of the distal appendage of centrioles (Fig. 2) and is required for docking of cargo-bearing vesicles from the Golgi apparatus to the cilium. Depletion of CEP83 thus impairs ciliogenesis by interfering with the first step of ciliary transport [123]. Mice with conditional knockout of *Cep83* in radial glial progenitor cells provided evidence for a role of the centrosome and centrosomal proteins in progenitor cell maintenance and patterning [124].

DCDC2/NPHP19

Mutations in *DCDC2* were first detected in patients with NPHP type 19 and early onset of liver fibrosis [20]. Subsequently, an isolated hepatic phenotype, namely, neonatal sclerosing cholangitis, was found to be caused by recessive mutations of *DCDC2* [125, 126] suggesting that DCDC2 carries an essential function in cholangiocytes and gives rise to a predominantly hepatic ciliopathy, which may include other organ manifestations. *Dcdc*2 knockout mice recapitulated the hepatic phenotype of affected patients and developed periportal liver fibrosis with abnormalities in biliary duct structure [20]. DCDC2 is a microtubule-binding protein that colocalizes with acetylated tubulin at the ciliary axoneme and mitotic spindle fibers in a cell cycle-dependent manner [20].

MAPKBP1/NPHP20

Mutations in *MAPKBP1* were shown to cause NPHP type 20, and extrarenal manifestations were not present in any of the identified patients [127, 128].

Animal Models

Several spontaneously occurring mouse models of mutated genes that exhibit an NPHP-like phenotype or a phenotype of SLS-like retinal degeneration were shown to represent orthologs of human NPHP genes. Examples are shown in Table 1, e.g., for the genes *NPHP2/INVS*, *NPHP3*, *NPHP6/CEP290*, *NPHP7/GLIS2*, *NPHP8/RPGRIP1L*, and *NPHP9/NEK8*. Furthermore, mouse models with generalized, or tissue-specific knockout of NPHP genes has been generated that reproduce renal, hepatic, neurological, skeletal, and/or developmental phenotypes of human ciliopathies. Zebrafish also recapitulate a wide array of human ciliopathy phenotypes and are therefore frequently applied as an animal model for nephronophthisis. Ciliopathy phenotypes in zebrafish include ventral body axis curvature and hydrocephalus, indicative of laterality defects as seen in humans with *situs inversus*. Zebrafish with knockdown of the orthologous genes of *CEP290/NPHP6* and *CEP164/NPHP15* displayed developmental brain defects, retinal dysplasia, and kidney cysts [110, 129]. As seen in patients with mutations of *IFT172*, zebrafish *ift172* morphants had skeletal defects [22]. Nephrocystin-4 is conserved in *C. elegans* and expressed in ciliated head and tail neurons of the nematode [130]. Upon knockdown, it exhibits a male mating phenotype, similar to the phenotype found upon knockdown of the polycystin-1 and polycystin-2 orthologs [131]. Localization of nphp-1 and nphp-4 to some of these ciliated neurons also overlaps with localization of the cystoprotein orthologs polycystin-1 (*lov-1*) and polycystin-2 (*pkd-2*) and with many orthologs of Bardet-Biedl syndrome (BBS) proteins [130, 132] similar to what has been described for *lov-1* and *pkd-2* mutants [131]. These data have been recently refined for specific neuronal cell types [130, 132], and the necessity of *nphp-1* and *nphp-4* for morphologic integrity of ciliated neurons in *C. elegans* was demonstrated [133, 134]. In addition, a role for *nphp-4* in life span of the worm has been demonstrated [135]. Evolutionary conservation of NPHP-RC proteins goes even further: Some have been conserved over more than 1.5 billion years of evolution from the unicellular organism *Chlamydomonas reinhardtii* to vertebrates. *Chlamydomonas reinhardtii* uses two motor cilia (flagella) for locomotion. Strikingly, nephrocystin-4 and at least six proteins mutated in BBS are conserved in *Ch. reinhardtii* where they constitute part of its basal body proteome [132, 136]. Defects of cystoprotein orthologs in *Ch. reinhardtii* have deficient intraflagellar transport and flagellar propulsion [137]. This further supports the notion that cystoproteins play a role in functional modules that are conserved throughout evolution.

Extrarenal Manifestations of NPHP

A prominent feature of NPHP is involvement of multiple organs in addition to the kidney (pleiotropy) (Table 1). Interestingly, organ manifestations of ciliopathies can be of developmental and degenerative nature. Infantile NPHP type 2 can be associated with *situs inversus* [6], liver fibrosis [138], or cardiac ventricular septal defect [6]. Furthermore, NPHP is frequently accompanied by tapetoretinal degeneration (Senior-Loken syndrome) [15, 16], cerebellar vermis hypo-/aplasia (Joubert syndrome) [17, 18], ocular motor apraxia type Cogan [139], mental retardation [50], liver fibrosis [19], or skeletal anomalies, such as cone-shaped epiphyses of the phalanges (Mainzer-Saldino syndrome) [21] or asphyxiating thoracic dystrophy (Jeune syndrome) [22, 140]. In some instances, there appears to be a genotype-phenotype correlation regarding pleiotropy and organ involvement. For example, there is involvement of the retina in most cases with mutations of *NPHP5* or *NPHP6*. Patients with mutations affecting IFT proteins mostly show prominent skeletal phenotypes. Patients with mutations in *ANKS6* and *DCDC2* are prone to developing liver fibrosis [20, 119].

Retinal Involvement (Senior-Loken Syndrome)

The renal-retinal involvement in Senior-Loken syndrome (SLS) can be explained by the fact that the primary cilium of renal epithelial cells is a structural equivalent of the connecting cilium of photoreceptor cells in the retina [141]. It was shown that nephrocystin-5 and nephrocystin-6 are expressed in the connecting cilia of photoreceptors [37, 102].

Cerebellar Vermis Hypoplasia (Joubert Syndrome)

In Joubert syndrome (JBTS), NPHP is associated with coloboma of the eye, with aplasia/hypoplasia of the cerebellar vermis causing ataxia, and with the variable symptoms of psychomotor retardation and episodic neonatal tachy-/dyspnea [17, 18, 142–144]. The radiographic feature of JBTS on axial magnetic resonance brain imaging is the so-called molar tooth sign of the midbrain-hindbrain junction [144, 145]. Ocular motor apraxia type Cogan, defined as the transient inability of horizontal eye movements in the first few years of life, may also be associated with JBTS. This symptom has been first described in patients with mutations in the *NPHP1* gene [76, 139] (causing JBTS type 4). To date, the monogenic causes of JBTS types 1–36 have been identified. Depending on the underlying mutated gene, involvement of other organ systems may be present (syndromic ciliopathies). There is multiple allelism for many JBTS genes, indicating that depending on the distinct mutation (allele), different ciliopathy phenotypes can arise, e.g., *CEP290* (JBTS type 5, NPHP type 6, SLS type 6, MKS type 4), *TMEM67* (JBTS type 6, NPHP type 11, MKS type 3, COACH syndrome), and *NPHP*1 (NPHP type 1, JBTS type 4, SLS type 1). Several JBTS genes are allelic to Meckel syndrome, a severe, embryonically lethal developmental ciliopathy characterized by cystic dysplasia of virtually all organ systems.

Liver Fibrosis

NPHP can be associated with periductal liver fibrosis [19, 146–148], as has been described for a patient with *NPHP3* mutation [47]. Furthermore, liver involvement is prominent in patients with mutations of *TMEM67* [149] (NPHP type 11), *ANKS6* [119] (NPHP type 16), and *DCDC2* [20] (NPHP type 19), which has also been described in patients with neonatal sclerosing cholangitis [125, 126]. The phenotypic spectrum of hepatic ciliopathies involves hepatomegaly, periportal fibrosis, and congenital hepatic fibrosis, as well as biliary dysgenesis and bile duct proliferation. Liver involvement is also present in autosomal recessive polycystic kidney disease (ARPKD). Bile duct involvement in these cystic kidney diseases is likely also explained by cilia-related mechanisms as the epithelial cells lining bile ducts (cholangiocytes) possess primary cilia [150].

Multi-organ Cystic Dysplasia with Severe Brain Malformations (Meckel Syndrome)

Within the spectrum of NPHP-associated ciliopathies, Meckel syndrome (MKS) is the most severe form. It leads to perinatal mortality with renal cystic dysplasia, occipital encephalocele, polydactyly, and biliary digenesis. Multiple recessive gene mutations have been identified, including in *MKS1* [151] and *MKS3* [152]. A Meckel-like phenotype has been described for truncating mutations of *NPHP3* [98], *NPHP6/CEP290* [104], and *NPHP8/RPGRIP1L* [54, 55]. MKS represents a ciliopathy that encompasses defects in most organs, and organ involvement is of developmental rather than degenerative nature. For instance, organ defects reveal cystic dysplasia of the kidneys, microphthalmia, liver bile duct dysgenesis, occipital encephalocele in the brain, and skeletal malformations, such as postaxial polydactyly are frequently seen [153]. The notion that MKS is at the most severe end of the clinical spectrum is supported by the finding that having two truncating mutations in *NPHP8/RPGRIP1L* causes MKS, whereas one "mild" mutation (missense rather than truncating) may cause the less severe phenotype of JBTS [104].

Cardiac Defects and *Situs Inversus*

In a patient with a mutation of *NPHP2*, a cardiac ventricular septal defect has been described [6]. Thus, the role of inversin for left-right axis specification known from mouse models was confirmed in humans [91, 154]. As this phenotype was associated with *situs inversus,* a cardiac ventricular septal defect may be viewed as a "heterotaxy" (left-right orientation) phenotype caused by the same mechanism [155]. The phenotypic combination of cystic kidney disease, *situs inversus*, and cardiac septal defects on the basis of *INVS* mutations has been observed in humans, mice, and zebrafish [6]. Congenital heart defects have also been observed in patients with *ANKS6* mutations [119]. Performing a forward genetic screen in mice, the group of Cecilia Lo identified mutations affecting ciliary proteins and/or ciliary signaling as a major pathogenic cause of congenital heart defects in mice [156], thereby strengthening the link between cilia and cardiac morphogenesis.

Skeletal Defects

NPHP can be associated with syndromic skeletal defects, including Jeune syndrome (asphyxiating thoracic dysplasia) [140, 157–159], Ellis-van Creveld syndrome [160], RHYNS syndrome (retinitis pigmentosa, hypopituitarism, NPHP, skeletal dysplasia) [161], Sensenbrenner syndrome (cranioectodermal dysplasia) [162, 163], and Meckel-Gruber syndrome [151, 152]. This strongly suggests a role of primary cilia in skeletal development. The association of NPHP with cone-shaped epiphyses of the phalanges is known as *Mainzer-Saldino syndrome* and was originally described in patients who also had retinal degeneration and cerebellar ataxia [21]. Interestingly, mutations in the ortholog of the intraflagellar transport protein IFT80 of *Chlamydomonas reinhardtii* were found to be the cause of *Jeune* syndrome [164] (Fig. 4), which emphasized the strong evolutionary conservation of "ciliopathy genes." When mutations in genes that encode other IFT proteins were identified in individuals with *Jeune*, *Mainzer-Saldino*, and *Sensenbrenner* syndromes, a link between IFT defects and skeletal ciliopathies was confirmed, most likely pointing toward an involvement of the sonic hedgehog signaling pathway in the pathogenesis of these ciliopathy phenotypes [22, 164, 165] (Table 1).

Bardet-Biedl Syndrome

Bardet-Biedl syndrome (BBS) is a syndromic ciliopathy characterized by pleiotropic organ manifestations and variable phenotypes that were first described by Laurence and Moon in 1866. To facilitate clinical diagnosis of BBS, diagnostic criteria have been established. Major criteria include renal anomalies, retinal degeneration (rod-cone dystrophy), obesity, polydactyly, intellectual disability, and hypogonadism. Minor criteria include cranioectodermal dysplasia (i.e., dental crowding, high-arched palate), cataracts, diabetes mellitus, hepatic fibrosis, congenital heart disease, and various neurological disorders (e.g., developmental delay, ataxia). The presence of four major criteria or the combination of three major and additional minor criteria defines the diagnosis of BBS. Studies have found renal involvement in >50% of BBS patients [166–168]. One British study in 350 BBS patients reported structural anomalies of the kidney in ~50% of patients and impaired renal function (CKD stages 2–5) in ~30% of pediatric patients and ~40% of adult patients with BBS [167]. The investigators observed that about 8% of BBS patients progressed to ESKD, mostly within the first five years of life [167]. Adult onset of CKD or ESKD was mainly from secondary causes, most notably type II diabetes mellitus and/or hypertension, which are frequent comorbidities in BBS patients. Structural anomalies of the kidney in BBS patients are diverse, including developmental malformations, hydronephrosis, interstitial fibrosis, and cystic dysplastic kidney disease. As observed in other ciliopathies, BBS is also characterized by genetic heterogeneity, and to date, mutations in 21 genes have been identified to cause BBS types 1–21. Some of those genes are allelic to other NPHP-RC (e.g., the genes *CEP290*, *TMEM67*, and *SDCCAG8*), while others have only been found in BBS patients. Mode of inheritance in

BBS is typically autosomal recessive; however, complex patterns, such as oligogenic inheritance, have been described [67]. Proteins encoded by BBS genes (i.e., BBS 1, 2, 4, 5, 7, 8, and 9) form a multiprotein complex (the BBSome, Fig. 3), which is localized at the ciliary base and is required for vesicle docking and ciliary entry of Golgi-derived proteins [169].

Diagnosis

Laboratory Studies

Patients with NPHP are often diagnosed only when an increased serum creatinine value is detected fortuitously. Patient history generally reveals prolonged nocturia since school age. Specific gravity of a morning urine specimen will be low. Renal ultrasound will then corroborate the diagnosis (Fig. 1b), which can be subsequently confirmed by molecular genetic diagnostics (www.renalgenes.org). A diagnostic algorithm for nephronophthisis has been suggested [170], but a positive diagnosis can now more easily be established by high-throughput exon sequencing [64] or whole-exome sequencing [62] (www.renalgenes.org). Hematuria, proteinuria, and bacteriuria almost never occur in NPHP, so that a bland urine sediment is a further diagnostic hint. Rarely, however, there can be an “overlapping” clinical phenotype presenting as a combination of NPHP-RC and nephrotic syndrome. In these instances, mutations have been detected in *ARHGDIA* [171] or *FAT1* [172].

Laboratory studies are needed to assess the severity of renal failure. Typically, patients have elevation of serum creatinine, blood urea nitrogen, and phosphorus, together with metabolic acidosis, hypocalcemia, electrolyte imbalance, and anemia. In SLS, retinitis pigmentosa is diagnosed by its specific findings on ophthalmoscopy including increased retinal pigment, attenuation of retinal vessels, and pallor of the optic disc. If retinitis pigmentosa is present, electroretinography and electrooculography can be used to evaluate severity. Retinal degeneration is characterized by a constant and complete extinction of the electroretinogram, preceding visual and fundoscopic signs of retinitis pigmentosa. Ophthalmoscopy should be performed in any patient with nephronophthisis to evaluate for signs of retinal degeneration. Laboratory assessment of liver function and hepatic ultrasonography are important to facilitate detection of patients with hepatic fibrosis. Skeletal involvement can be detected by thorough clinical examination. In patients with infantile NPHP, echocardiography is advisable.

Imaging

The most useful imaging technique in NPHP is renal ultrasonography. The kidneys are of normal or moderately reduced size and show increased echogenicity; loss of corticomedullary differentiation; and, in later stages, cyst formation at the corticomedullary border of the kidneys [9] (Fig. 1b). Garel and associates have described medullary cysts in 13 of 15 children studied at the time of renal failure (mean age 9.7 years) [173]. Roentgenography contributes little to the diagnosis of the disease. Medullary cysts can sometimes also be demonstrated on magnetic resonance imaging or computed tomography [174, 175]. Histology is characteristic but not pathognomonic in NPHP, since cysts may be absent and tubulointerstitial disease can be nonspecific. Renal biopsy can be circumvented as an initial procedure due to the availability of molecular genetic diagnostics in NPHP (www.renalgenes.org). If genetic diagnostics do not detect a molecular defect, the diagnosis can be based on the combined results of typical clinical history with polyuria, polydipsia, and anemia; the classical appearance of the kidneys on ultrasound; and renal histology. A thorough pedigree analysis should be documented for each of three successive generations, to rule out autosomal dominant MCKD/ADTKD.

Molecular Genetic Diagnostics

Knowledge of causative gene mutations, technical advances in next-generation sequencing technology, and cost reduction for genetic testing have made definite molecular genetic diagnostics possible (www.renalgenes.org) and applicable for routine diagnostics in clinical settings. In patients with the suspected diagnosis of NPHP-RC based on clinical presentation and/or renal ultrasound imaging, identification of the underlying gene mutation succeeded in up to 50–70% of cases through application of high-throughput barcoded exon sequencing [64] or whole-exome sequencing (WES) [62]. Trio WES analysis in multiple family members of different generations can further increase the likelihood of finding the causative mutation and can help with the interpretation of ambiguous results. A recent study showed that in approximately one-third of pediatric patients awaiting renal transplantation, a monogenic kidney disease can be identified [61], Nine of the 104 total patients (9%) were clinically categorized as having renal cystic ciliopathy, and 78% of those were molecularly diagnosed by WES [61]. Retrospective analysis of genetic studies demonstrated that the likelihood of finding the causative mutation is higher in cases with familial occurrence of renal disease, in patients with extrarenal manifestations, when there is parental consanguinity and in cases with early onset of disease [60, 61]. Homozygous deletions in the *NPHP1* gene account for approximately 21% of all NPHP cases, whereas mutations in the other genes are far less common (Table 1). Therefore, it is a reasonable approach to attempt detection of homozygous deletions in *NPHP1* as a first step, since testing is fast, cheap, and technically well established and has approximately a one in five chances of finding the causative mutation. If no *NPHP1* mutation is identified, there are two possible ways to proceed. First, one could use targeted, multiplex PCR-based screening of the next 10–15 most frequently mutated genes (gene panel sequencing [64]). This approach is fast and relatively cheap because it allows parallel sequencing of multiple patient samples in each assay. Alternatively, one could perform WES of all coding regions in the human genome ("the exome") with the advantage that in WES, the analyzed gene set is unrestricted and therefore genes that were not suspected based on the patient's clinical presentation ("phenocopies") will also be included in the analysis. Presently, cost reduction for clinically certified WES has made this option feasible for more patients. However, because in ~30% of NPHP patients mutation analysis will fail to identify a causative mutation, finding no mutation does not exclude the diagnosis of NPHP. For instance, complex genomic rearrangements cannot be detected by WES due to technical limitations. Therefore, further analysis using, e.g., genome-wide analysis of copy number variants (CNVs) [176] or whole-genome sequencing may be indicated in patients with negative test results. Presently, most of those latter techniques are used in research settings, although as research progresses the number of patients for whom we can offer a definite molecular diagnosis by genetic testing may further increase. In summary, it is logical to apply a step-wise approach for molecular diagnostics in patients with suspected NPHP-RC.

Genetic Counseling

Molecular genetic testing should only be performed with patient/parent consent within the guidelines of the National and International Societies for Human Genetics (http://www.ashg.org/press/healthprofessional.shtml). Acceptance of molecular genetic diagnostics among patients and families may increase in the United States due to the recent passing of the Genetic Information Nondiscrimination Act (GINA) by congress (http://www.ashg.org/press/ginaupdate.shtml). Before genetic counseling, a thorough pedigree analysis to distinguish recessive (early-onset) from dominant (late-onset) disease is mandatory, and extrarenal organ involvement should be interrogated. Since asymptomatic potential carriers of recessive defects should not be examined by molecular genetic diagnostics, unaffected siblings below 25 years of age should be re-evaluated yearly for urinary concentrating ability and by renal ultrasound. If symptoms evolve and serum creatinine increases, molecular genetic diagnostics following informed consent is warranted, to allow early prevention of complications such as electrolyte disturbances, dehydration, anemia, and growth retardation. If a transplant recipient's renal histology suggests NPHP and a living related donor is considered, molecular genetic diagnostics may help to exclude or detect renal disease within the potential donors. Recurrence of disease has never been reported after renal transplantation in NPHP patients. Prenatal diagnosis can be performed by direct genetic testing, if the specific mutation has already been characterized in an affected sibling.

Differential Diagnosis

On histopathology, NPHP and MCKD have to be differentiated from other forms of interstitial nephropathies like chronic pyelonephritis or drug injury. In oligomeganephronic dysplasia, kidney size is reduced, and histology is distinct from NPHP. The paucity of urinary abnormalities, the frequent lack of hypertension, normal kidney size, and the localization of renal cysts (if present) readily differentiate variants of the NPHP and MCKD from recessive or dominant polycystic kidney disease. Finally, medullary sponge kidney [177] can easily be distinguished from NPHP or MCKD, since the former does usually not lead to chronic kidney disease and demonstrates calcifications and calculi on renal ultrasound. The presence of a normal urine sediment distinguishes NPHP from monogenic proteinuric kidney diseases, such as steroid-resistant nephrotic syndrome or Alport syndrome.

Prognosis and Therapy

There are no specific therapies for NPHP. Therapy is directed toward abatement of symptoms and toward the correction of electrolyte, acid-base, and water balance disturbances, typically by a (pediatric) nephrologist. Hypokalemia may contribute to polyuria, so if detected, oral potassium supplementation may alleviate this problem. Metabolic acidosis should be corrected, and renal osteodystrophy and secondary hyperparathyroidism are treated with adequate calcium supplementation, phosphorus restriction, phosphate binders, and/or vitamin D therapy. Anemia should be treated with iron supplementation and erythropoietin, growth retardation may require administration of growth hormone, and hypertension (if present) should be treated. Adequate nutrition should be maintained with the help of a dietician. Psychological counseling of the patient and his/her parents is an integral part of therapy, because of the potential for poor self-image associated with growth retardation and chronic disease, as well as to help with the difficulties from the need to comply with complicated medications and dietary restrictions. Most patients will require renal replacement therapy by dialysis and/or renal transplantation in childhood or adolescence. Outcomes after renal transplantation are usually favorable in NPHP patients [178], and disease recurrence in the transplanted kidney has never been reported.

Despite intense research, no specific treatment for NPHP has been identified. Several experimental treatment strategies have been tested in cell culture and in in vivo models; however, none has proven to be beneficial in clinical studies to date. For example, roscovitine, a selective inhibitor of cyclin-dependent kinases, has been successfully used to mitigate the renal cystic phenotype in mouse models of NPHP-RC where the cell cycle is dysregulated [110, 179]. Furthermore, loss of function of the gene *DCDC2* was shown to cause dysregulation of the Wnt signaling pathway; in zebrafish, knockdown of the orthologous gene phenocopied the human disease, and the fish responded to treatment with a Wnt inhibitor [20]. Gattone et al. have shown that the renal cystic phenotype of *pcy* mice, which is the equivalent of human NPHP type 3, can be mitigated by treatment with the vasopressin V2 receptor antagonist OPC31260 [101]. Similar results can be found in a *pkd2* mouse model [180]. These benefits of the V2 receptor antagonists are thought to be mediated by reduction of intracellular cAMP levels [50]. In adult patients with ADPKD who fulfill specific criteria and are at risk for rapid progression, two large clinical studies demonstrated beneficial effects for the vasopressin V2 receptor antagonist tolvaptan [181, 182]. However, this treatment is not approved for patients younger than 18 years of age and has not been tested in NPHP patients; furthermore, potential benefits of tolvaptan are uncertain in these patients as the pathogenesis of NPHP differs significantly from that of ADPKD. An important future challenge will be the development of NPHP-specific therapies that capitalize on what has been learned in preclinical studies.

Abstract

Autosomal dominant tubulointerstitial kidney disease (ADTKD) is a recently defined entity characterized by tubular atrophy, interstitial fibrosis, and development of chronic kidney disease. Different forms of ADTKD can manifest in childhood; however, due to the slow progressive nature of this condition,

renal failure usually develops in adulthood. Initially, ADTKD was known as medullary cystic kidney disease (MCKD). However, after the identification of mutations in *Uromodulin* (*UMOD*) as one of the causative genetic defects for MCKD, it became apparent that only approximately 20% of patients with *UMOD* mutations develop renal cysts and that the medulla is not a specific location for the cysts when observed. Therefore, the name "medullary cystic kidney disease" was considered misleading and contributing to underdiagnosis of this condition. Other terms used for the same condition included familial juvenile hyperuricemic nephropathy (FJHN), hereditary interstitial kidney disease, and tubulointerstitial nephritis. In order to replace these unspecific and misleading names with a more descriptive and accurate term which would also simplify diagnosis, the term "autosomal dominant tubulointerstitial kidney disease" (ADTKD) was created (Eckardt KU, Alper SL, Antignac C, Bleyer AJ, Chauveau D, Dahan K et al, Kidney Int 88:676–683, 2015). A major challenge of ADTKD is the nonspecific nature of clinical and pathological characteristics. To make the correct diagnosis, a family history is helpful and consistent with a dominant pattern of inheritance. Recently, other genes mutations (*Mucin-1, HNF1B, Renin, SEC61A1*) have also been associated with ADTKD, providing evidence that, in fact, the term ADTKD refers to a heterogeneous disease spectrum with overlapping renal phenotypes caused by at least five different genes (Devuyst O, Olinger E, Weber S, Eckardt KU, Kmoch S, Rampoldi L et al, Nat Rev Dis Primers 5(1):60, 2019). In this chapter, the genetic and clinical heterogeneity, of the pathogenesis, and potential therapeutic approaches for this condition will be discussed.

ADTKD - medullary cystic kidney disease; HNF1B - TCF2; UMOD - Tamm Horsfall protein

Introduction

In 1971, Bennett and Gardner first described patients with cysts of the renal medulla and named the condition medullary cystic kidney disease (MCKD) [1, 3, 4]. Over 30 years later, dominant mutations in the gene encoding Uromodulin (*UMOD*) were published in patients with MCKD type 2 [5–8]. *UMOD* mutations were also identified in patients with familial juvenile hyperuricemic nephropathy (FJHN) and glomerulocystic kidney disease (GCKD), showcasing a wide clinical spectrum caused by mutations in one gene [7]. Even prior to the discovery of *UMOD* mutations, it was noticed that the two previously named conditions MCKD2 and FJHN (which both were found later to be caused by *UMOD* mutations) displayed significant clinical overlap with polyuria, hyperuricemia, gout, tubulointerstitial fibrosis, progressive chronic kidney disease (CKD), and renal failure between 25 and 70 years of age [9]. Because overlapping phenotypes were also found with single allele mutations in *Mucin-1* (*MUC1*), *hepatocyte nuclear factor 1β* (*HNF1B*), *Renin* (*REN*), and *SEC61A1,* these conditions have now all been combined as autosomal dominant tubulointerstitial kidney disease (ADTKD) with a subclassification based on the underlying gene mutation [1, 10–13] (Table 1). Most of these genes when mutated either accumulate in renal tubular cells due to protein misfolding (e.g., UMOD, MUC1, REN) or participate in the translocation process of proteins to the endoplasmic reticulum (ER) (e.g., SEC61A1) [2]. In the ER, proteins undergo multiple modifications such as removal of the signal peptide, *N*-glycosylation, disulfide bond formation, and protein folding via oxidoreductase and chaperones. Correctly folded and modified, proteins leave the ER and then enter the Golgi apparatus and the secretory pathway. If this process is perturbed, ER stress and the unfolded protein response (UPR) are triggered, resulting eventually in cellular apoptosis and

AKI acute kidney injury, *BP* blood pressure, *DCT* distal convoluted tubule, *ER* endoplasmic reticulum, *FEUrat* fractional excretion of uric acid, *HNF1B* hepatocyte nuclear factor 1B, K^+ potassium, *LFT* liver function test, Mg^{2+} magnesium, *MUC1* Mucin-1, *REN* Renin, *SEC61A1* α1 subunit of transport protein SEC61, *TAL* thick ascending limb, *UMOD* Uromodulin organ failure. Due to the histopathological similarities between ADTKD and nephronophthisis, these conditions are sometimes also described by pathologists as a dominant version of nephronophthisis. Whereas UMOD is mostly expressed in tubular cells of the thick-ascending limb of Henle's, the other gene products are mostly expressed in the intermediate and distal nephron. Typically, mutations in *UMOD*, *MUC1*, and *REN* are confined to renal defects, although mutations in *HNF1B* and *SEC61A1* frequently lead to extrarenal manifestations (Table 1) [1].

Epidemiology of ADTKD

Given the rarity of ADTKD and the likely underdiagnosis of the condition, it is difficult to provide accurate epidemiological data. Presently, there are no obvious differences in ADTKD prevalence based on gender, nationality, or ethnicity. It is likely that ADTKD is disproportionately underdiagnosed in African-Americans given their overall reduced access to medical care and that they have other frequent causes of CKD such as *APOL1*-related kidney disease [14]. Among the different causes of ADTKD, it appears that mutations in *UMOD* and *MUC1* represent the most common forms of the disease. Initially, the prevalence of ADTKD-*UMOD* was reported as 1.67 cases per million [1, 15]. However, a recent study that identified *UMOD* mutations in five kidney transplant recipients among a total of 911 patients suggests that ADTKD-*UMOD* is more common than originally suspected [16]. In a recent CKD patient cohort, about 9% were found to have a monogenetic disease and 3% had a *UMOD* mutation, accounting for about 0.3% of all CKD patients in this group [17]. Together, among the estimated 37 million CKD patients in the United States, there may be approximately 1.1 million patients with a *UMOD* mutation. In an Irish cohort, 2.6% of CKD patients had a *UMOD* mutation [18]. In a separate Irish cohort, mutations in *UMOD*, *MUC1*, and *HNF1B* were found in 0.54% of patients with renal failure [19]. In an English CKD cohort, it was estimated that ADTKD has a prevalence of 16 per million with an ADTKD-*UMOD* prevalence of 9 per million (representing approximately 1% of patients with CKD stages 3–5) [20]; thus, in this population, ADTKD may be the most common monogenetic kidney disease after ADPKD and collagen IV mutations. In the United States, ADTKD-*MUC1* mutations are estimated to have a prevalence of 0.7 per million individuals, while in Ireland a prevalence of 4 per million has been estimated [2]. Together, these data suggest that ADTKD, and in particular ADTKD-*UMOD,* is fairly common and still underdiagnosed, due to a lack of specific clinical characteristics. The prevalence of *HNF1B* point mutations and deletions in the general population is unknown. It is likely that many cases are incorrectly diagnosed due to the variable phenotype, incomplete gene penetrance, and the high frequency of *de novo HNF1B* deletions. Among patients with structural kidney abnormalities, the *HNF1B* mutation rate varies between 5% and 31% and constitutes the most frequent cause of kidney dysplasia of monogenic origin in pediatric cohorts. Diagnosis in children can often lead to diagnosis that was unrecognized in affected family members [11, 21]. Among the causes of ADTKD, mutations in *REN* and *SEC61A1* are much less common with about 30 identified ADTKD-*REN* families and only two ADTKD-*SEC61A* families [12, 13, 22].

Presentation of ADTKD

Clinical Characteristics

Given the new unifying terminology, an increasing number of ADTKD cases have been published, suggesting that ADTKD is one of the more common monogenic kidney diseases [17, 20, 23]. A main reason that ADTKD has been overlooked and underdiagnosed is that clinical, laboratory, and pathological findings are nonspecific. To make the correct diagnosis, it helps to look at the holistic presentation in the context of all clinical findings. Common features of ADTKD are progressive CKD, absent-to-mild proteinuria, normal or mildly elevated blood pressure, and normal (early diagnosis) to small (later diagnosis) kidneys (Table 2). The most prominent feature of

Table 2 Clinical findings in ADTKD patients

Autosomal dominant inheritance
Progressive worsening of chronic kidney disease
Unremarkable urine sediment
No proteinuria or only mild proteinuria
During the early stages no severe hypertension
Early-onset hyperuricemia or gout
Enuresis or nocturia in children
Urinary concentration defect, polydipsia-polyuria in severe forms
Early chronic kidney disease in severe forms in children
Renal ultrasound shows normal or small-sized kidneys
Lack of exposure to medications causing tubulointerstitial nephritis

ADTKD is the autosomal dominant inheritance pattern (Table 2). However, the absence of a family history does not rule out the condition, as *de novo* mutations may occur, in particular for ADTKD caused by *HNF1B* mutations [24]. A few cases of ADTKD have had two mutations in *UMOD* in the same individual, leading to a more severe phenotype [25]. Penetrance within families can be variable, although disease usually appears in all affected family members if they live long enough. Disease severity and age of onset are quite variable even within a family that has the same mutation. For certain genetic subcategories of ADTKD, extrarenal manifestations may be prominent. For example, *HNF1B* mutations commonly present with a range of extrarenal symptoms, and rarely the tubulointerstitial kidney disease is the sole manifestation [26, 27]. Therefore, the term ADTKD-*HNF1B* should be reserved for patients with *HNF1B* mutations in which the tubulointerstitial kidney disease is the prominent presentation [1]. Mutations in *SEC61A1*, which encodes the α1 subunit of the SEC61 translocon pore, usually result in more syndromic forms of kidney disease with intrauterine or postnatal growth retardation, neutropenia (causing recurrent skin infections), congenital anemia, and small, dysplastic kidneys which may contain cysts [13]. Age of onset is variable and often dependent on the ADTKD subtype. Whereas ADTKD-*UMOD* patients may present with gout and CKD in the late teen years, ADTKD-*MUC1* patients usually present with CKD (only) in the early 20s. ADTKD-*HNF1B* may be present in fetuses or infants as the most common cause for increased bilateral renal echogenicity. Genitourinary abnormalities are often found in childhood, and gout can present in the teenage years in these patients [27, 28]. Maturity-onset diabetes of the young (MODY), associated with *HNF1B* mutations, usually does not present until the third decade of life. Studies have shown that in children with *HNF1B* mutations, kidney disease led the clinical presentation, whereas in adults MODY-type-diabetes-related symptoms predominated [28–30]. Finally, ADTKD-*REN* can present in early infancy with hyperkalemia, CKD, and anemia.

Chronic Kidney Disease

The rate of decline of renal function is quite variable, often dependent on the genetic mutation causing ADTKD [24, 26, 31]. The age of onset for renal replacement therapy varies significantly among and within families with ranges between the ages of 20 years and 80 years. Most ADTKD patients require initiation of renal replacement therapy between 30 and 50 years of age. In rare cases, renal replacement therapy is required in childhood [32]. CKD can present in childhood with smaller kidneys, increased echogenicity, hyperuricemia, or gout [32–38]. Creatinine may be only mildly elevated. While end stage kidney disease due to ADTKD typically occurs after 30 years of age, it can occur in childhood and has been described as early as 6–7 years of age with *UMOD* and *HNF1B* mutations [23, 26, 37]. ADTKD-*MUC1* patients typically develop end stage kidney disease earlier than ADTKD-*UMOD* patients (46 vs. 54 years, respectively) [39]. While ADTKD-*HNF1B* usually causes renal failure between the age of 25 and 70, infants with *HNF1B* mutations and severe kidney hypoplasia-dysplasia may develop end stage disease early in life. As REN regulates renal fluid and electrolyte absorption, patients with *REN* mutations are at higher risks for volume depletion and hypotension, which may aggravate the risk for CKD.

Urinary Concentration Defect and Enuresis

Certain forms of ADTKD result in urinary concentration defects and enuresis. In a large family with ADTKD-*UMOD,* the maximum urine osmolality was 593 ± 76 mOsm/kg compared to 918 ± 239 mOsm/kg in unaffected individuals [40]. In the same ADTKD-*UMOD* kindred, 10 out 39 family members had enuresis [40]. The urinary concentration defect is thought to stem from accumulation of mutant UMOD in the thick ascending limb of Henle (TAL) which disturbs TAL function and leads to polyuria [41]. The urinary concentration defect has also been described in animal models of ADTKD-*UMOD* [42]. As a consequence of the chronic volume depletion, the proximal tubule increases fluid absorption in a compensatory fashion and absorbs more uric acid in parallel which contributes to the hyperuricemia associated with ADTKD.

Hyperuricemia and Gout

UMOD and *HNF1B* mutations can result in early onset of gout as early as 3 years of age. A dominant family history of gout is present in up to 75% of male and 50% of female ADTKD patients and suggests the possibility of *UMOD* or *HNF1B* mutations [24]. In male ADTKD patients, gout can present early in life (range 3–51 years) [24, 37]. ADTKD-*UMOD* patients typically present much earlier with gout than ADTKD-*MUC1* patients (30 vs. 67 years, respectively) [39]. Frequently, gout presents in childhood prior to the onset of significant renal impairment. While hyperuricemia and gout may lead to the diagnosis, both of them are not a diagnostic requirement for ADTKD. In fact, hyperuricemia and gout may occur after the onset of severe CKD [24].

Hypomagnesemia

Refractory hypomagnesemia of renal origin has been described with various types of *HNF1B* mutations [43]. As the hypermagnesuria in these patients is usually not associated with hypercalciuria, the impairment of renal Magnesium (Mg^{2+}) reabsorption occurs in the distal nephron and not the TAL. In the distal convoluted tubule, HNF1B binds to the promoter of the *FXYD2* gene which encodes the γ subunit of the Na^+/K^+-ATPase; mutations in *FXYD2* cause autosomal dominant hypomagnesemia, and HNF1B is thought to regulate *FXYD2* [44]. While hypomagnesemia can be observed in children, the frequency of hypomagnesemia in patients with *HNF1B* mutations increases with age and is predominant after the second decade of life [43, 45, 46]. In adults with *HNF1B* mutations, hypokalemia has been frequently observed [25].

While hypomagnesemia is not a common problem in ADTKD-*UMOD* patients, deletion of UMOD in mice also resulted in hypermagnesuria and hypomagnesemia [47]. UMOD increases the cell surface abundance of the apical Mg^{2+} channel TRPM6. Urinary UMOD levels are higher in hypomagnesemic mice suggesting a feedback mechanism where UMOD enhances TRPM6 activity in a Mg^{2+}-deficient state. Why magnesium levels are normal in most patients with *UMOD* mutations is unknown.

Hypertension

Most ADTKD patients do not present with hypertension; however, with more advanced CKD, hypertension is common [40].

Anemia

Anemia is typically found in patients with *REN* mutations and is unrelated to the degree of GFR impairment [12]. The cause for the anemia is not well understood. It is thought that Renin-producing cells may have the capability to secrete erythropoietin and that loss of REN function leads to anemia [48]. The anemia in ADTKD-*REN* patients usually resolves during puberty, correlating with the rise of testosterone.

Imaging

In most forms of ADTKD, kidney ultrasound studies are nonspecific and nondiagnostic. In most patients, kidney size is initially normal. As ADTKD progresses, kidney size declines and cysts can occur in varying numbers and sizes [2]. Overall, the frequency of cysts in ADTKD is not thought to be more common than in other “non-cystic” forms of chronic kidney disease [24, 49]. In some ADTKD patients, glomerular cysts have been described [7, 36]. In ADTKD-*HNF1B* patients, large, hyperechogenic kidneys may be present prenatally [28]. Bilateral cystic kidney dysplasia occurs in 20–30% of cases caused by *HNF1B* mutations [29]. Renal dysplasia and glomerulocystic kidney disease may also present in fetuses with ADTKD-*HNF1B* nephropathy [50].

Laboratory Studies

The urinary sediment is usually normal or may reveal microhematuria. Proteinuria is absent or mild [24, 26, 31]. *UMOD*, *REN*, and *HNF1B* mutations can cause hyperuricemia. Elevated uric acid levels, even early in childhood, tend to suggest these forms of ADTKD. Most of these patients have an abnormally low fractional excretion of uric acid ($Fe_{Urat} < 5\%$, normal FE_{Urat} is $>5\%$). However, Fe_{Urat} is frequently reduced in any type of CKD with a GFR < 80 ml/min/1.73 m^2 and, therefore, is not a reliable diagnostic criteria for ADTKD [24, 41]. Changes in Renin and Aldosterone levels are not diagnostic for ADTKD-*REN*. Studies have found lower urinary secretion of UMOD in ADTKD-*UMOD* patients, although this test is not readily clinically available [6, 32, 38].

Genetic Testing

The gold standard for diagnosis of ADTKD is identification of a causative mutation. Relatives of an affected individual have a 50% likelihood to have the mutation. Genetic testing is recommended in adults in whom ADTKD is suspected, which will inform the ability to donate a kidney and/or assist in prepregnancy planning [2]. However, given the lack of specific therapeutic options to treat ADTKD at this point, testing of unaffected minors is discouraged [51]. Many practitioners think that the choice of testing with the potential psychologic burden with a disease diagnosis with no specific therapy is best left to the child once they come of age. A quality of life survey in adults with ADTKD showed that “ADTKD has a substantial effect” on their life; 23% of diagnosed patients thought about it daily, 26% weekly, 26% monthly, and 26% less than monthly [52]. While anxiety was similar between ADTKD-affected and control individuals, the affected patients were more frequently depressed. Therefore, it may be appropriate to leave the question of genetic testing to the individual once they are old enough to decide for themselves.

The decision about whether to do genetic testing is difficult and complex and should be openly discussed with the family. Many families are thankful for a diagnosis even without a specific therapy as it often resolves a long search for a cause of their disease. Among a group of 55 individuals who were genetically diagnosed with ADTKD with no foreknowledge about their renal disease, 93% were happy that testing was performed, 5% remained neutral, and only 2% were unsatisfied [52]. A definitive diagnosis prevents the need for further diagnostic tests which reduces further cost and time expenditure. Additionally, genetic testing may be considered in families with a high prevalence of gout as therapy with allopurinol or febuxistat may prevent gout [2]. Furthermore, a definitive diagnosis can provide benefits in children with ADTKD-*REN* or ADTKD-*HNF1B*. In the case of ADTKD-*REN,* one can screen for anemia and treat with erythropoietin if needed. Hypotension and hyperkalemia could be treated with agents such as Fludrocortisone. Patients could be counseled on appropriate precautions to avoid volume contraction and to avoid NSAID use to decrease risks of AKI. In ADTKD-*HNF1B*, hyperuricemia, which presents in about a third of patients, can be treated with allopurinol or febuxistat. These patients can be also screened for hypomagnesemia and hyperglycemia. Also, postkidney transplant immunosuppressive management can be modified to reduce the risk of new-onset diabetes mellitus after transplantation (NODAT), which is more prevalent in ADTKD-*HNF1B* patients [53]. As ADTKD-*HNF1B* patients have a high likelihood of underlying hypomagnesemia, use of tacrolimus is discouraged as it may exacerbate hypomagnesemia [43]. Hypomagnesemia and steroid exposure may trigger development of NODAT, which reduces survival of the kidney allograft [54–56]. Parents and possible candidates for testing (dependent on age) should be involved in a discussion about costs, test interpretation, and future implications. In the United States, an ADTKD diagnosis may affect future health and/or life insurance coverage. As new ADTKD treatments become available, early genetic diagnosis may become the goal to initiate this therapy as early as possible. As ESKD often happens later in life, pediatric nephrologists may be critical in providing these newer therapies.

Preclinical studies have shown promise for future therapeutic strategies [57].

Genetic testing for *UMOD*, *REN*, and *HNF1B* is well established in clinical practice and can be performed by commercial genetic testing laboratories. *HNF1B* mutations can consist of large deletions requiring a multiplex ligation-dependent probe amplification (MLPA) assay to avoid missing the mutation by sequencing of the *HNF1B* gene. Identifying *MUC1* mutations may be challenging. *MUC1* mutations are usually a single base pair insertion within the variable nucleotide tandem repeat (VNTR) which consists of 60 base pair motifs encoding for 20 amino acids. *MUC1* has 25–125 VNTR repeats translating into 1.5 and 7.5 kb of sequence. Moreover, the VNTR is a highly GC-rich region, and as the insertion occurs variably within the VNTR for each family, detecting *MUC1* mutations is highly challenging [10]. Only very few laboratories including the Broad Institute in Boston are capable of reliably performing MUC1-genetic testing (https://www.broadinstitute.org/rare-diseases/muc1-kidney-disease-mkd). Different diagnostic tools for identifying *MUC1* mutations/insertions in the VNTR include SNaPshot minisequencing, single molecule real-time sequencing, and immunostaining using antibodies that detect mucin 1 neoproteins (MUC1-fs) in kidney biopsies and urinary cells [58–60]. While none of these assays have become routine testing yet, the noninvasive detection of MUC1-fs in urinary cells may be the most useful diagnostic tool in the future [60]. Despite advances in molecular diagnostics, mutations in *UMOD*, *MUC1*, *REN*, and *HNF1B* are only responsible for 50–60% of all ADTKD cases, indicating that mutations in other not yet identified genes may cause ADTKD [2]. In a recent study of an ADTKD cohort of 726 patients, *UMOD* mutations were the most common identified in 38.4% followed by MUC1 mutations in 35.1% [39].

Pathology Findings

Renal biopsies for ADTKD show interstitial fibrosis, tubular atrophy, and thickened glomerular basement membranes [9, 24, 26, 49] (Fig. 1a). Lamellation and thickening of tubular basement membranes and tubular dilatation are typically observed [6, 9]. These findings help to differentiate ADTKD from tubulointerstitial fibrosis observed with other types of progressive CKD that occurs due to matrix accumulation from tubular cells [61, 62]. Renal cysts can be identified although they are not considered to be more commonly seen than in other “non-cystic” forms of chronic kidney disease [24, 26, 31, 49]. As cysts are more frequently found in patients with more advanced ADTKD than those with early stages of disease, cysts are not likely to be causing the decline in renal function [1]. Glomeruli are usually not involved, although rare patients may have secondary focal and segmental glomerulosclerosis or with glomerulocystic kidney disease [7, 36]. Immunofluorescent studies for complement and immunoglobulins may exclude other causes of CKD but cannot be used to directly diagnose ADTKD. Intracellular cytoplasmic inclusions of lamellated aggregates derived from mutant proteins may be detected (Fig. 1b). Immunostaining for UMOD or MUC1-fs may reveal focal, coarse, and dense accumulation of mutant protein aggregates [10, 63] (Fig. 1c, d). The intracellular mutant protein accumulation in ADTKD-*UMOD* explains the lower urinary UMOD concentration seen in these patients [6, 32, 38]. The ability to detect lower urinary and/or plasma levels of UMOD and to detect urinary MUC1-fs offers the possibility for future noninvasive-testing strategies. Electron microscopy imaging may show fibrillar material in expanded stacks of ER of the thick ascending limb, most likely representing accumulation of mutant UMOD protein [63, 64] (Fig. 1e, f).

Differential Diagnosis

Infrequently, nephronophthisis (NPHP) may present in young adults or later in life [65–67] and as such may be misidentified as ADTKD. The recessive inheritance pattern with NPHP should help to distinguish NPHP from ADTKD, except in rare cases of pseudodominant inheritance of NPHP [65, 68]. Patients with ADPKD typically have much larger kidneys and more prominent cyst development than ADTKD. Biopsy findings in

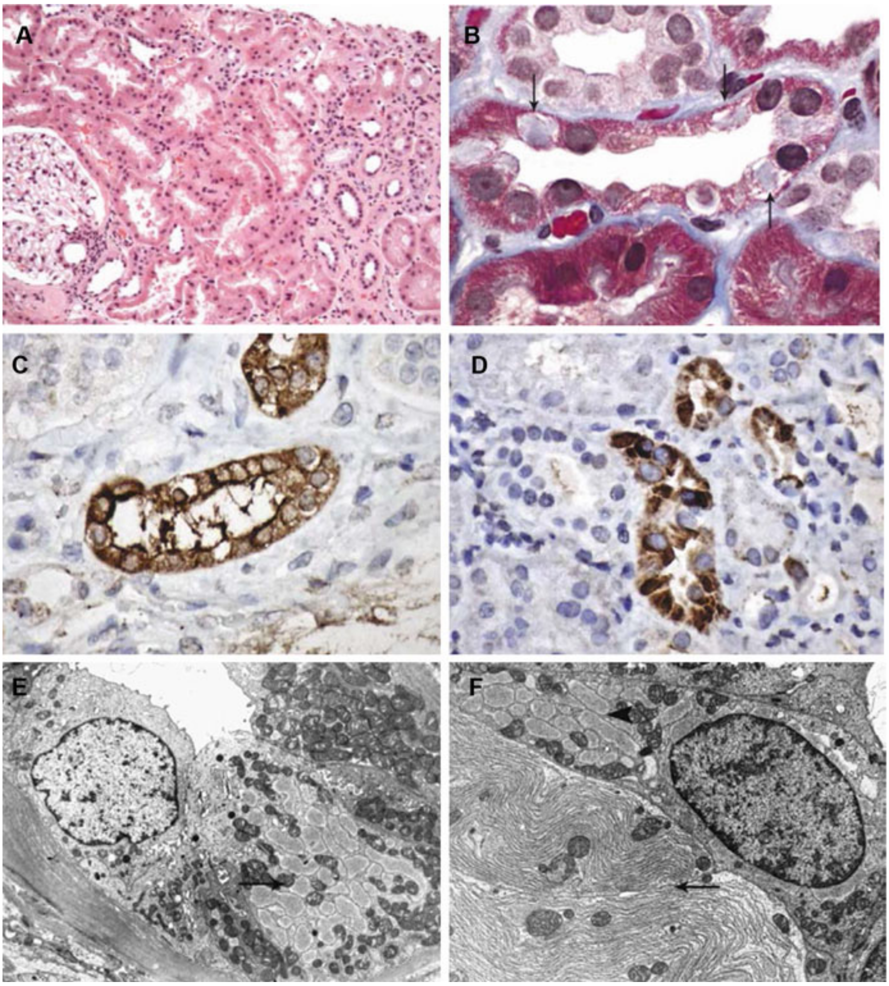

Fig. 1 **Renal histology of ADTKD-*UMOD*.** (**a**). At lower magnification, the renal cortex of an ADTKD-*UMOD* patient shows focal patchy tubular atrophy, interstitial fibrosis, and mild interstitial inflammation. No tubulitis is observed (Hematoxylin and eosin, original magnification x200). (**b**) At higher magnification, focal intracytoplasmic inclusions of lamellated trichrome blue material (arrows) are seen which contrast with the red-stained cytoplasm (Masson trichrome, original magnification x600). (**c**) In a control kidney, UMOD is detected in a homogenous, diffuse pattern in the cytoplasm and stronger along apical membranes (original magnification x600). (**d**) In an ADTKD-*UMOD* patient, focal, coarse, dense clusters of mutant UMOD accumulate within the thick ascending limb (original magnification x600). (**e**) Electron microscopic imaging showed dilated cisternae of the ER with accumulation of granular, electro-dense storage material. The tubular membrane is thickened and lamellated (Electron micrograph, original magnification x4000). (**f**) Electron microscopic imaging of a thick ascending limb cell displays hyperplastic bundles of the ER (arrow) with few intervening mitochondria and areas of dilated ER that contain elevated levels of material (Electron micrograph, original magnification x4000). All figure panels were published in [63]

ADTKD may resemble other forms of tubulointerstitial kidney disease caused by autoimmune processes, medication toxicity (NSAIDs, calcineurin inhibitors, and lithium), or tubulointerstitial nephritis and uveitis syndrome [2]. Extrarenal manifestations are rare in ADTKD except with *HNF1B,* and *SEC61A1* mutations. In children, congenital abnormalities of kidney and urinary tract

(CAKUT) of other origin are in the differential diagnosis. Presence of normal amniotic fluid, bilateral normal-small sized kidneys, often with cysts and extrarenal involvement with ADTKD, may help to differentiate between the former and other causes of CAKUT [27–30, 45]. That said, ADTKD-*HNF1B* patients may present with oligo-/anhydramnios and/or massively enlarged and/or cystic kidneys that mimic autosomal recessive polycystic kidney disease (ARPKD) or early ADPKD. These phenotypes may occur as HNF1B is a master regulator of *PKHD1* and *PKD2* genes [69]. Genetic testing can help clarify the diagnosis [70]. Atypical forms of ADPKD-ADTKD due to heterozygous *DNAJB11* mutations (with normal-sized kidneys, kidney fibrosis, slowly progressing CKD, and high prevalence of renal cysts) should be considered in patients with no mutations in *UMOD*, *MUC1*, *REN*, *HNF1B*, *or SEC61A1* [71]. A one allele loss of *DNAJB11* perturbs maturation and trafficking of polycystin-1 and UMOD, with retention of UMOD in the TAL, similar to ADTKD-*UMOD* [71]. Homozygous *DNAJB11* mutations result in Ivemark II syndrome, with oligohydramnios and severe renal-hepatic-pancreatic dysplasia [72]. Renal histology with the latter syndrome also reveals interstitial fibrosis and multiple renal cysts. Mutations in *PAX2* and mitochondrial DNA can also result in tubulointerstitial kidney disease similar to what is seen in ADTKD [73, 74]. The ocular findings in patients with renal coloboma syndrome (caused by *PAX2* mutations), if present, should differentiate these patients from ADTKD [75]. In mitochondrial diseases, only maternal transmission occurs and as such may differentiate the former from ADTKD. Other causes of hyperuricemia such as Lesch-Nyhan (caused by X-linked *HPRGT* mutations) are usually accompanied by more severe developmental and behavioral problems such as self-mutilation and choreoathetosis than in ADTKD patients [76]. Patients with hyperuricemia and kidney stones but normal neurologic development may have Kelley-Seegmiller syndrome which is a milder form of Lesch-Nyhan syndrome, caused by only partial inactivation of the *HPRGT* gene [77].

Specific Forms of ADTKD

ADTKD-UMOD Is Caused by Mutations in Uromodulin

For over 140 years, Uromodulin (UMOD), also called Tamm-Horsfall protein, has been known to be the most abundant protein in human urine [78]. The Italian physician Carlo Rovida first described UMOD as a product of renal tubular cells forming hyaline casts in the tubular lumen in 1873 [78]. In 1950, Igor Tamm and Frank Horsfall described an abundant urinary mucoprotein which inhibited viral hemagglutination and was subsequently named Tamm-Horsfall protein [79]. In 1985, a 85 kDa glycoprotein was isolated from the urine of pregnant women and was found to inhibit human T-cells and monocyte activity. Therefore, the protein was named Uromodulin [80]. The gene *UMOD* (OMIM 191845) is located on chromosome 16p12.3 and encodes the 85 kDa glycoprotein Uromodulin (UMOD) which is exclusively synthesized in the kidney where it is expressed within the TAL and the early distal convoluted tubule [5, 80–86] (Fig. 2a). UMOD is the major constituent of hyaline casts. UMOD has a high carbohydrate content (30%) and many cysteine residues and forms large protein aggregates [87]. In 1987, investigators reported that Tamm-Horsfall protein and UMOD are the same protein [81]. UMOD is synthesized as a precursor of 640 amino acids (Fig. 2b). It contains a signal peptide encoded by 24 amino acids which targets the nascent protein to the ER and is cleaved during protein maturation. The mature urinary protein is 616 amino acids long and consists of 48 cysteine residues which form 24 disulfide bridges [81, 88]. The signal peptide is followed by four epidermal growth factor (EGF)-like domains, a cysteine-rich domain of unknown function (called D8C domain), and a bipartite C-terminal Zona Pellucida (ZP) domain (Fig. 2b). Whereas the EGF-like domains are thought to be important for protein-protein interaction, the ZP domain is crucial for protein assembly into larger, extracellular, supramolecular polymers (Fig. 2c, d)

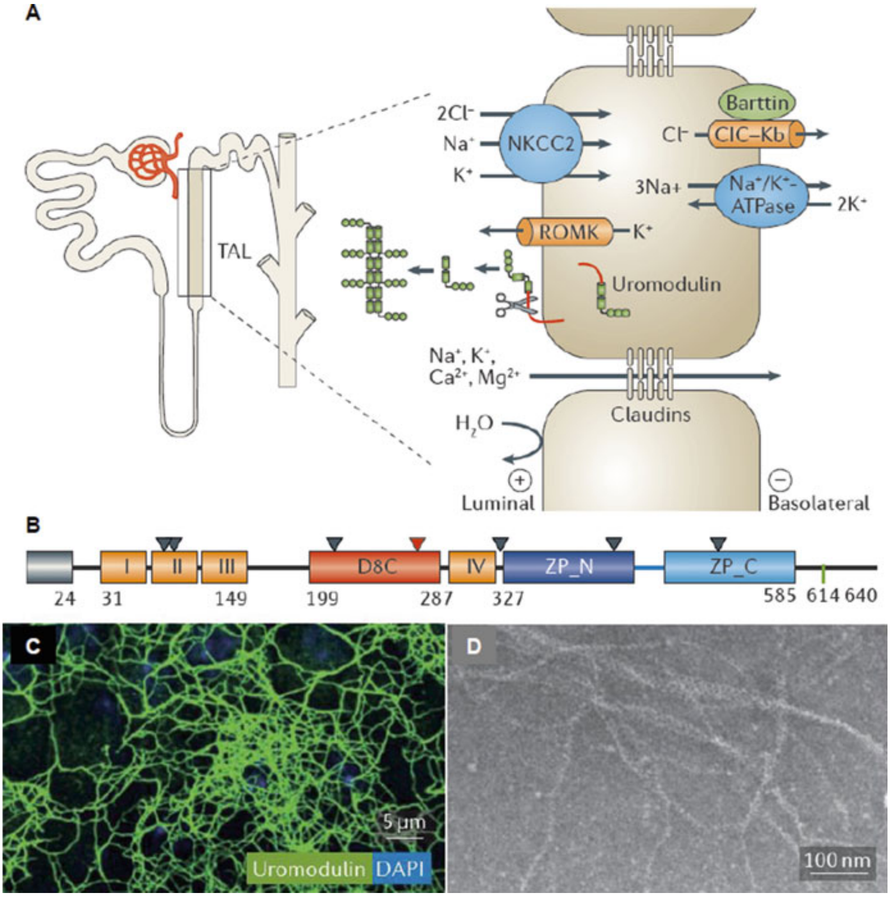

Fig. 2 **UMOD protein sequence, expression, and function**. (**a**) UMOD is synthesized in the thick ascending limb and the distal convoluted tubule. UMOD is targeted to the apical membrane where it is cleaved and released into urine by the serine protease hepsin. In urine, UMOD forms polymers and enhances NKCC2 and ROMK activity in the TAL. Recycling of K^+ via ROMK contributes to the lumen-positive transepithelial voltage which is the major driving force for paracellular Ca^{2+} and Mg^{2+} absorption. (**b**) The protein structure of UMOD includes a signal peptide (grey), four EGF-like domains (orange) which are important for protein-protein interaction, a cysteine-rich domain of unknown function (red), and a bipartite Zona Pellucida domain (ZP-N and ZP-C shown in different shades of blue). Position 614 (green) is a glycosylphosphatidylinositol-anchoring site. The seven *N*-glycosylation sites are indicated by arrowheads. A high mannose chain on residue Asn275 is identified by a red arrowhead. (**c**) Immunofluorescence imaging shows a network of UMOD filaments (green) covering a monolayer of primary TAL cells from a microdissected mouse kidney. (**d**) A transmission electron microscope image displays UMOD polymers secreted by primary mouse TAL cells. All figure panels were published in [78]

[89]. In addition to apical expression of UMOD and urinary secretion, UMOD is also thought to be released from the basolateral membrane of TAL cells into the bloodstream [83, 92], although plasma concentrations are approximately 1000-fold lower than in the urine [90–92].

Protein Function

UMOD is the most abundant protein in human urine with 50–150 mg generated per day and forms a porous 3D matrix (Fig. 2c, d) [93, 94]. UMOD plays a role in renal development and is expressed in the kidney between the 8th and 16th week of gestation, increasing steadily in quantity with maturation of the TAL [95]. UMOD is synthesized in the TAL (90%) and the DCT (10%), two nephron segments with significant roles in tubular transport of sodium, potassium, calcium, magnesium, and chloride [84, 96]. UMOD protects against urinary tract infections, acute kidney injury, and kidney stone formation and contributes to water homeostasis, renal salt handling, and immunomodulation [87, 97–101]. In addition, UMOD may play a role in the water impermeability of the TAL by forming a hydrophobic, gel-like structure which covers the apical membranes [100]. Mice lacking UMOD (*Umod*$^{-/-}$) have impaired urinary concentration ability after water deprivation [102]. Studies in *Umod*$^{-/-}$ mice also revealed that UMOD protects against urinary tract infections by binding to type1-fimbriated *E. coli*. UMOD interferes with bacterial adhesion and internalization into the uroepithelium [97, 103]. UMOD was subsequently confirmed to be protective against UTIs in a large human study that showed that higher urinary UMOD levels conferred a lower risk of UTIs [104, 105]. *Umod*$^{-/-}$ mice also develop urinary Ca^{2+}-containing crystals which cause renal calcinosis, ureteral obstruction, and hydronephrosis [98, 106, 107]. UMOD is thought to prevent renal crystal formation in a complex with other urinary proteins such as osteopontin, as a polyanionic macromolecule by coating the crystal surface and preventing crystal nucleation [108, 109]. In addition, UMOD may prevent formation of Ca^{2+} crystals by increasing membrane expression of the apical renal calcium channel, transient receptor potential cation channel subfamily V member 5 (TRPV5), by interfering with the channel's endocytosis, thus blocking hypercalciuria [99]. In humans, Ca^{2+} and uric acid stone formers excrete less urinary UMOD. In control individuals, a linear correlation exists between urinary UMOD and Ca^{2+}; however, this correlation was not found in stone formers, suggesting that stone formers are unable to secrete more UMOD with higher urinary Ca^{2+} concentrations [110]. In another study, stone formers had a 32% lower urinary UMOD concentration and a lower sialic acid content than control patients suggesting a role for UMOD and/or UMOD glycosylation in prevention of nephrolithiasis [111]. A genome-wide-association-study (GWAS) also identified a single nucleotide polymorphism (SNP) within *UMOD* which was associated with protection against formation of Ca^{2+}-containing kidney stones [112]. UMOD seems to have pleiotropic effects on tubular ion channels and also affects blood pressure. Exogenous UMOD enhances Na^{+}-K^{+}-$2Cl^{-}$-cotransporter (NKCC2) and Na^{+}-Cl^{-}- cotransporter (NCC) function and causes hypertension. However, mutant UMOD interferes with NKCC2 trafficking to the apical membrane of TAL cells, thereby contributing to TAL dysfunction, a urinary concentration defect and modest volume depletion [42, 84, 101, 102, 113]. Specific SNPs in the *UMOD* gene in healthy individuals are associated with increased UMOD secretion and ion transporter activity. Mice overexpressing WT UMOD displayed a 80% higher UMOD secretion and subsequently developed hypertension and left ventricular hypertrophy due to higher phosphorylated (activated) NKCC2 [101]. A role for UMOD in blood pressure regulation has been confirmed using *Umod*$^{-/-}$ mice which displayed lower blood pressures and higher urinary Na^{+} excretion compared to wild-type animals [114]. Correlatively, a study showed that a human cohort with the SNP rs12917707 (G/G allele) in *UMOD* resulted in reduced kidney function and left atrial remodeling [115]. UMOD also modifies ion channels such as the apical potassium and magnesium channels ROMK and TRPM6, respectively [47, 116]. Urinary and plasma UMOD levels correlate with renal mass and function and have been utilized as early biomarkers and predictors of acute kidney injury [90, 117–120]. A lower spot urine UMOD/creatinine ratio prior to cardiothoracic surgeries correlated with a higher risk of more severe AKI after the procedures [119, 120]. *Umod*$^{-/-}$ mice displayed delayed recovery after ischemic injury [121]. Lower urinary and serum UMOD levels have also been observed in patients with early kidney allograft failure [122, 123]. An association between urinary UMOD secretion and estimated glomerular filtration rate (eGFR) has been postulated [91, 117, 124]. Urinary UMOD likely reflects tubular activity with 24 h-urinary-UMOD levels being directly proportional to urine volume and kidney size [125]. Genetic variants near the *UMOD* gene are associated with higher renal UMOD expression, hypertension, eGFR, and/or decline of renal function [125–133]. Plasma UMOD levels correlate with creatinine clearance in CKD patients and could potentially help to track progression of disease in CKD patients [90–92]. Even in children with non-ADTKD CKD, serum UMOD levels were reliable indicators for CKD progression [134, 135].

Outside of ADTKD, common variants in *UMOD* are associated with higher risks of other types of CKD and end stage kidney disease [126, 127, 133]. Genome-wide association studies identified *UMOD* promoter and *UMOD* variants associated with declines in renal function and risks of CKD in the general population [112, 126, 128, 133, 136, 137]. The *UMOD* variant rs13333226 was found to be associated with increased risks of diabetic nephropathy [138]. Other *UMOD* variants were found to increase urinary UMOD expression which correlated with salt-sensitive hypertension and kidney damage [101, 125]. Another *UMOD* variant, rs4293393, also results in increased urinary UMOD levels but is associated with a lower risk of UTIs [105]. It is possible that high frequency of this ancestral latter UMOD allele (which may lead to hypertension and kidney damage later in life) protects against UTIs during the earlier years and thereby improves fitness and reproduction. There are conflicting data whether high urinary UMOD has a protective effect or aggravates chronic kidney disease. While some contend that urinary UMOD increases tubular salt absorption and thus may worsen hypertension, others suggest that UMOD bolsters immunity. UMOD modulates the innate immune system by binding of cytokines, monocytes, dendritic cells, and immunoglobulins via Toll-like receptor 4 (TLR4) [121, 139–143], and as such, UMOD deficiency causes a state of inflammation [141]. UMOD also modifies granulopoiesis and enhances macrophage phagocytic activity in response to AKI [139]. UMOD promotes transition from the proinflammatory to the healing stage during recovery. Cross-talk from the TAL to the proximal tubule and the TAL has been proposed with UMOD-inhibiting chemokine signaling and thereby reducing damage to the neighboring proximal tubule [121, 144]. UMOD also appears to have pleiotropic effects on metabolism and longevity. In a cohort of patients with coronary artery disease, higher serum UMOD levels correlated with decreased mortality [145]. In a follow-up study, higher serum UMOD levels were associated with a favorable metabolic profile with lower rates of hypertension, diabetes mellitus, heart failure, and 10-year mortality [146]. Lower serum UMOD levels also correlate inversely with HgbA1c and serum glucose values [138, 146–148]. Lower urinary and serum UMOD levels were also identified in patients with type 1 and type 2 diabetes mellitus and diabetic nephropathy [149–155]. It remains unclear if and how higher serum UMOD concentrations exert a protective effect on metabolism whereas higher urinary UMOD are associated with higher rates of hypertension and chronic kidney disease. One study showed that systemic UMOD inhibits oxidative stress by inactivation of the TRPM2 channel, and thus, serum UMOD could provide some systemic protection [156]. Together, UMOD function in urine and serum could be different, accounting for the differences in apparent protective versus deleterious effects of UMOD.

Recent data have begun to identify how tubular UMOD secretion is modified. One study found that the Ca^{2+} sensing receptor (CaSR) reduces UMOD secretion [157]. Using mouse models, *Casr*-activating mutations decreased urinary UMOD secretion, whereas inactivating mutations increased UMOD secretion. Humans treated with cinacalcet also had lower urinary UMOD secretion [157]. Additionally, hypomagnesemia increased urinary UMOD secretion in mice [47]. Moreover, high dietary NaCl intake increased renal UMOD mRNA and protein expression in rats [158]. Other studies suggest that urinary secretion of UMOD may also be salt sensitive in humans [131, 159]. Finally, high protein intake increases UMOD secretion while antidiuretic and thyroid hormone reduce UMOD secretion [93, 160, 161]. HNF1B binds to specific *Umod* chromatin DNA target sites and increases mouse UMOD expression. Mice lacking *Hnf1b* have significantly reduced urinary UMOD secretion [69].

Clinical Presentation

Based on the inverse relationship between urine osmolality and uric acid levels, ADTKD-*UMOD* patients are thought to have a urinary concentration defect and mild salt-wasting phenotype [41]. Children with ADTKD-*UMOD* also have a higher incidence of enuresis than the general population [40]. About 25–87% of patients with ADTKD-*UMOD* present with hyperuricemia, gout, and a low $FE_{Urat} < 5\%$ [24, 162]. A family history of gout is very common in these patients and is attributed to a higher compensatory fluid (and urate) absorption in the proximal tubule (given the distal urinary concentrating defects and chronic state of volume depletion) leading to hyperuricemia. Compared to other ADTKD forms, *UMOD* mutations commonly cause early onset of hyperuricemia and gout which should raise suspicions for ADTKD-*UMOD* [1, 24]. Gout appears much earlier in ADTKD-*UMOD* than in ADTKD-*MUC1* patients (mean ages of 30 vs. 67 years, respectively) [39]. A younger age of onset for gout correlated with an earlier age of onset for ESKD [23]. Age of ESKD onset in ADTKD-*UMOD* ranged between 25 and above 70 years with a median of 54 years. Men usually develop gout more frequently (75%) than women (50%), and median age of ESKD occurs at 50 years of age for men versus 60 years for women [37]. Another study showed that ESKD prior to the age of 30 years is rare and that women develop ESKD later than men [23]. Most ADTKD-*UMOD* patients have missense mutations, and as is often true of other genetic diseases, the type and localization of missense mutation may affect disease progression, particularly if a partially functional gene product is made [37]. The few ADTKD-*UMOD* patients with complete gene deletions typically have a worse clinical outcome [24]. A few cases of ADTKD with homozygous *UMOD* mutations have been identified, and as expected, these patients frequently develop ESKD several decades earlier than the heterozygous family members consistent with a dose-dependent mutant UMOD effect [25, 162, 163]. A dose-dependent effect of *UMOD* mutations has also been shown in different ADTKD-*UMOD* mouse models [164, 165]. The *UMOD* mutation affected the ratio of low versus high molecular UMOD glycoforms which correlated with the age of onset of ESKD and may provide an in vitro scoring system [23]. Alternatively, the position of the *UMOD* mutation may determine the onset of symptoms with patients carrying *UMOD* mutations in the second or third EGF-like domains presenting earlier than those with more distal *UMOD* mutations [37]. A clinical *UMOD*-score has recently been developed to identify the likelihood of ADTKD-*UMOD* [39]. The *UMOD*-score includes positive points for 1) a family history of early gout (<40 years) consistent with autosomal dominant inheritance (+2), 2) CKD of unknown origin (+2), 3) age at gout onset (<30 year +3 points; >30 year +1 point), 4) hyperuricemia (>8.41 mg/dl +3 points, <8.41 mg/dl +1 point), and 5) histological findings compatible with ADTKD (+2 points). Factors that lower the *UMOD*-score include proteinuria/hematuria (−1), diabetes mellitus/uncontrolled hypertension (−1), and enlarged kidneys/cysts (−1). Patients with a *UMOD*-score > 8 are encouraged to undergo a *UMOD* mutation analysis. Those with a score between 5 and 7 are encouraged to have urinary UMOD levels assessed, and if urinary levels are low *UMOD* mutation analysis is recommended. If a facility is unable to test for urinary UMOD levels, assessment of a *UMOD* gene analysis is recommended for patients with a *UMOD*-score > 5 [39].

Pathophysiology

UMOD mutations cause protein misfolding [7, 64, 166]. Proper tertiary protein folding is a requirement for correct sorting in the ER and subsequent processing in the Golgi apparatus [167, 168]. In kidney biopsies of ADTKD-*UMOD* patients, large intracellular deposits were described (Fig. 1c, d), colocalizing with markers of the ER, and loss of UMOD on the apical membrane [6, 7, 63, 64]. Usually, UMOD is targeted to the apical membrane and then released by the serine protease Hepsin into urine where UMOD forms polymers [169] (Fig. 2). Mice lacking Hepsin have significantly reduced Umod secretion with Umod accumulation in kidney cells. Mutant forms of UMOD are not appropriately trafficked to the apical membrane and are also retained in tubular cells [6, 32, 38] (Fig. 3). Patients with ADTKD-*UMOD* have reduced urinary UMOD levels consistent with impaired trafficking and urinary secretion of the mutant protein [6, 32, 38, 64]. Mutant UMOD that is secreted into the urine can also exert a dominant-negative effect on WT UMOD protein, interfering with WT UMOD polymerization [6, 7, 38, 170]. Over 135 *UMOD* mutations, distributed mostly in the N-terminal epidermal growth factor (EGF)-like domains I-IV and the cysteine-rich D8C domain, have been identified [78]. The vast majority of *UMOD* mutations are missense mutations, and <5% of mutations are in-frame deletions. While no frequent or founder *UMOD* mutations has been identified to date, approximately 60% of all UMOD mutations affect 1 of the 48 conserved cysteine residues and, as such, disrupt formation of at least 1 of the 24 intramolecular disulfide bonds, leading to protein misfolding. Cellular and murine *Umod* mutant models have shown impaired trafficking to the plasma membrane, decreased secretion, accumulation and retention of mutant UMOD in the ER, often resulting in apoptosis [7, 42, 64, 166, 170–174]. To date, six different mutant mouse models for ADTKD-*UMOD* have been generated, all of which lead to accumulation of mutant UMOD in the ER, reduced urinary UMOD secretion, TAL damage with urinary concentration defects, and chronic loss of kidney function [42, 164, 165, 175, 176]. Histology in the mutant mouse models recapitulates the findings from kidney biopsy samples from humans with ADTKD-*UMOD* (Fig. 1). Proteomic analysis of mutant *Umod* mice has shown aberrant activation of the UPR, ER stress, and mitochondrial dysfunction [165, 175, 177, 178] (Fig. 3). Thus, ADTKD-*UMOD* may represent an ER storage disease leading to upregulation of UPR and apoptosis in response to accumulation of misfolded protein within the ER

Fig. 3 Mutant versus wild type UMOD trafficking and function in renal tubules. Mutant UMOD is retained within the tubular cells of the TAL and the DCT and aberrantly activates different cellular pathways. Accumulation of mutant UMOD in the endoplasmic reticulum (ER) causes ER stress and stimulates the unfolded protein response. Chronic induction of the unfolded protein response causes activation of inflammation and cell death. Downstream consequences of mutant UMOD are defective autophagy and altered mitochondria morphology and dynamics. Mutant UMOD which escapes the ER quality control or proteasomal degradation can undergo trafficking to the apical membrane. Secreted mutant UMOD may interfere with polymerization of wild-type UMOD. This figure was published in [2]

(Fig. 3) [172, 179]. A number of chemical agents, enumerated below, decreased apoptosis in vitro but failed to do so in vivo. In addition to UPR activation, the C147W *Umod* mouse had reduced autophagy and elevated levels of proapoptotic mediators including TNF-α [176]. A different mutant ADTKD-*UMOD* mouse model revealed early onset of inflammation followed by pro-fibrotic signals that sustained disease progression [180]. Interfering with TNF signaling by administering a fusion protein that blocked the TNF receptor (TNFR) ameliorated apoptosis, fibrosis, and kidney failure in that mouse [176]. Mutant UMOD also affects tubular transport of Na^+, K^+, Ca^{2+}, and Mg^{2+} by interfering with NKCC2, ROMK, TRPV5, and TRPM6 trafficking and activity [42, 47, 99, 113, 116]. The different ADTKD-*UMOD* mouse models support the notion that many of the defects associated with *UMOD* mutations lead to mutant forms of UMOD protein that cause a dominant negative effect on the wild-type protein; these findings are supported, because complete *Umod* knockout mice have no abnormal histological kidney findings [181].

Diagnostic Testing

In addition to mutation analysis for *UMOD*, which is provided by many commercial genetic-testing laboratories, assessment of urinary UMOD levels has been a good screening tool to help in the diagnosis of ADTKD-*UMOD*. Spot urine for UMOD is also recommended as a part of a *UMOD*-score [39]. Unfortunately, urinary UMOD analysis may not be available in many countries, in which case *UMOD* mutation analysis has been recommended [39]. Kidney biopsies can be specifically stained for UMOD to demonstrate UMOD storage defects in the TAL (Fig. 1) [63].

Therapeutic Approaches

In cell culture models of ADTKD-*UMOD*, aberrant apoptosis was partially blocked by colchicine, topiroxostat, probenecid, and the chaperone, sodium 4-phenylbutyrate (4-PBA) [170, 172, 179]. The latter improved secretion of mutant UMOD. However, in two different *Umod*-mutant mouse models, the beneficial effects of 4-PBA were not reproduced [182]. Blockade of proapoptotic TNF-α signaling in the C147W *Umod* mouse with the recombinant fusion protein TNFR:Fc prevented decline of renal function in the mutant mice [176]. Administration of topiroxostat, a xanthine oxidase inhibitor, to mutant C112Y UMOD cells, decreased apoptosis rates [179]. Stimulation of autophagy by mTOR inhibitors also increased secretion of mutant C147W UMOD in vitro [176]. A small molecule that targets TMED9, a cargo receptor, was shown to reroute one mutant UMOD protein variant into lysosomes for degradation in tissue culture [57] and as such has therapeutic potential.

ADTKD-MUC1 Is Caused by Mutations in Mucin-1

In contrast to UMOD which has been well known to the Nephrology community, Mucin-1 (MUC1) has surfaced more recently to the nephrology community as the causative gene for ADTKD-MUC1 [10, 183]. The *MUC1* gene (OMIM 158340) is located on chromosome 1q22 and encodes a highly glycosylated epithelial transmembrane protein which is strongly expressed along the TAL, distal nephron, and collecting ducts (Fig. 4a) [184–186]. MUC1 is involved in intracellular signaling, cell-cell, and cell-matrix interactions [187–189] (Fig. 4b). The MUC1 protein contains a N-terminal subunit consisting of signal peptide, a variable nucleotide tandem repeat (VNTR), a sea urchin sperm protein, enterokinase, agrin (SEA) domain, and a C-terminal subunit containing extracellular, transmembrane, and cytoplasmic domains (Fig. 4c) [189]. The hallmark of Mucins is the VNTR domain (Fig. 4c). Each VNTR repeat contains 20 amino acids with the entire VNTR region encoding a repetitive sequence of amino acids which is crucial for the extensive *O*-glycosylation of MUC1 [189]. The length of the VNTR region ranges from 20 to 125 repeats dependent on the inherited paternal and maternal alleles. Similar to UMOD, MUC1 is secreted in the urine [91, 190]. In contrast to UMOD, which is a glycosylphosphatidylinositol-(GPI)-anchored membrane protein, MUC1 is a cell membrane-associated protein, with the N-terminal subunit of MUC1 being tethered to the MUC1 C-fragment in

Fig. 4 Wild type and mutant MUC1 protein sequence and expression. (**a**) MUC1 is expressed in the TAL, the distal nephron, and the collecting ducts. (**b**) MUC1 is a cell membrane-associated protein, with the N-terminal subunit of MUC1 being tethered to the MUC1 C-fragment in a noncovalent fashion, which can undergo autoproteolysis. MUC1 covers the apical surfaces of epithelial cells in multiple organs. The protein contains an N-terminal and extracellular α subunit which contains a variable number of tandem repeats (VNTR), and each tandem repeat (TR) encodes 20 amino acids (AA). The VNTR is very important for *O*-glycosylation of MUC1. The C-terminal cytoplasmic β subunits anchor MUC1 to the membrane and possibly the cytoskeleton. The extracellular MUC domains protect luminal epithelial surfaces. The MUC1 intracellular domains are involved in signaling via phosphorylation and protein-protein interactions. (**c**) Wild-type MUC1 protein structure includes the signal peptide (SP) (blue) which is required for MUC1 translocation to the ER, the VNTR (red), the sperm protein, enterokinase, and agrin (SEA) domain (orange) and the transmembrane domain (TM) (gray). Auto-proteolytic cleavage in the SEA domain forms the heterodimeric MUC1 protein complex consisting of the N-terminal extracellular α subunit and the C-terminal cytoplasmic β subunits and leaves a transmembrane (TM) domain in the plasma membrane. The mutated MUC1-fs protein contains the SP domain, part of the WT VNTR, and a novel VNTR segment (green) after the frameshift mutation (triangle). MUC1-fs do not include C-terminal sequences required for cellular signaling, post-translational processing, membrane targeting, and MUC1 recycling. (This figure was published in [2])

a noncovalent fashion [191]. While UMOD is cleaved at the C-terminus of the protein and released into the ultrafiltrate, MUC1 undergoes autoproteolysis in the SEA domain, and the N-terminal part of MUC1 is then released into the tubular filtrate [191, 192] (Fig. 4a, b). The identification of mutations within *MUC1* as responsible for a variant of ADTKD was complicated by the location of the *MUC1* mutations within the VNTR region. In most ADTKD-*MUC1* patients, a cytosine duplication occurs within any one of the VNTR repeats within the tract of seven cytosine residues. The insertion of another cytosine residue within the VNTR creates a frameshift and results in a newly encoded frameshift peptide (MUC1-fs). These mutations occur at the C-terminal of the signal sequence, so that the MUC1-fs protein is properly trafficked to the ER, but later accumulates within tubular cells (see below). As the VNTR is a highly GC-rich region and as the insertion occurs in a different unit of the VNTR for each family, the detection of the *MUC1* insertions has been highly challenging [10].

Protein Function

MUC1 is detected in the developing kidney and is upregulated in renal cell carcinoma [193, 194]. Similar to UMOD, MUC1 forms polymers in urine and contributes to a viscous, mucous layer protecting the epithelial surface of renal tubules and in other organs [188, 195, 196]. MUC1 interacts with epidermal growth factor receptor and correlates with the mitogen-activated protein kinase activation in the mammary gland, raising concern for a role of MUC1 in breast cancer [197]. MUC1 appears to also have a causative role in pancreatic and colon cancer and is a target for immunotherapy with a vaccine against the protein [198, 199]. MUC1 promotes metastasis in other types of cancer, and antibody therapy is under development to prevent metastases [200–202]. MUC1 promotes metastasis by interacting with the lectin galectin-3 [203, 204]. Despite strong MUC1 expression in breast, lung, and gastrointestinal tissues, patients with ADTKD-*MUC1* do not have a higher incidence of breast, lung, or gastrointestinal cancer [31]. Similar to UMOD, MUC1 appears to protect against AKI by activating hypoxia-inducible factor 1α and β–catenin signaling [205, 206]. In addition, calcium-containing kidney stone-formers were found to have lower urinary MUC1 levels compared to nonkidney stone formers [186]. Mechanistically, MUC1 stabilizes the abundance of the apical calcium channel TRPV5 in the luminal membrane, thereby reducing the risk for hypercalciuria and calcium-containing crystals in normal individuals [186].

Clinical Presentation

Patients with ADTKD-*MUC1* typically present earlier than those with ADTKD-*UMOD* and have gout and/or hyperuricemia less frequently [39]. ADTKD-*MUC1* patients typically have a bland urine sediment, and no increased risks of UTIs, kidney stones, or polyuria [31]. The presentation is often more subtle than in ADTKD-*UMOD* with slow, progressive CKD as the main features [2]. In the United States, the Broad Institute, in Boston, is the only clinically certified laboratory to directly test for *MUC1* mutations. Other potential diagnostic tools are currently under development, including detection of the MUC1-fs protein by immunofluorescence in urinary cells [60]. Single-molecule real-time sequencing and SnapShot minisequencing also seem to be promising means for eventually diagnosing ADTKD-*MUC1* [49, 58, 59].

Pathophysiology

The chromosomal locus for mutations that cause forms of ADTKT-*MUC1* (formerly known as MCKD type 1) was well-known for years, and many candidate genes were identified [9, 207, 208]. Extensive mutation analysis of candidate genes with Sanger sequencing did not reveal the causative gene mutations, including in *MUC1* [209]. At that time, it was impossible to sequence through long stretches of repetitive DNA through the *MUC1* VNTR (up to 7.5 kB) (Fig. 4c). Many years later by applying cloning, capillary sequencing, de novo assembly, and a probe-extension assay, causative *MUC1* mutations were identified as a cytosine duplication within any one of the VNTRs resulting in the mutant MUC1-fs protein [10, 49]. All VNTRs after the frameshift mutation have a new sequence including one cysteine and six basic amino acid residues [10]. This results in MUC1-fs being very cysteine rich, highly positively charged, and natively unfolded. The frameshift mutation leads to a premature stop codon soon after the altered VNTR [10]. This results in a loss of the MUC1 C-terminus which is important for posttranslational processing, forward trafficking to the apical membrane, and recycling of MUC1. The MUC1 C-terminus is required for MUC1 transport via exosomes to Flotillin-2-

organized lipid rafts on the cell membrane [210]. The C-terminus is also crucial for the extensive MUC1 *N*- and *O*-glycosylation. To date, six different *MUC1* frameshift mutations, mostly nucleotide insertions and duplications within the VNTR, have been described [10, 49, 60], all of which result in expression of a MUC1-fs protein [10, 31, 49, 58, 59, 211–213]. Similar to UMOD, the intracellular accumulation of MUC1-fs is thought to cause the pathological effects of the disease. Proteomic analysis of extracellular vesicles shed by the renal tubular cells into the urine from ADTKD-*MUC1* patients found a reduction of proteins involved in vesicle transport and membrane dynamics of exosomes and lysosomes [214]. Consistent with the notion that accumulation of a dominant negative MUC1-fs protein is responsible for the pathological findings, mice with complete *Muc1* deletion do not develop progressive kidney disease [215]. While the abnormal MUC1-fs protein is detected in many different organs including breast, stomach, and sebaceous glands, the kidney is the only organ to develop pathological findings. While the reason for the kidney-specific sensitivity to MUC1-fs is unknown, some have speculated that MUC1-fs may interact with another tubular protein only present in the kidney [10, 31, 58].

Diagnostic Testing

Direct detection of MUC1 mutations is available at the Broad Institute in Boston (https://www.broadinstitute.org/rare-diseases/muc1-kidney-disease-mkd). SNaPshot minisequencing may soon be used to identify the abnormal insertions in the MUC1 VNTR. Alternatives include single molecule real-time sequencing, and development of specific antibodies that detect mutant MUC1-fs in kidney biopsies and urinary cells [58–60].

Therapeutic Approaches

The small molecule BRD4780 has been identified to improve MUC1-fs secretion by targeting a cargo receptor called TMED9 [57]. This small compound reroutes the MUC1-fs-mutant protein to lysosomes for degradation and may eventually be used clinically in patients with ADTKD-*MUC1*.

ADTKD-HNF1B Is Caused by Mutations in Hepatocyte Nuclear Factor 1β

Hepatocyte nuclear factor 1β (HNF1B) is a DNA-binding transcription factor of 557 amino acids encoded by the *HNF1B* gene (formerly known as *TCF2*) (see Table 1) on chromosome 17q12. HNF1B regulates embryonic development and tissue-specific gene expression in epithelial organs including the kidney, liver, intestine, genital organs, and pancreas [216].

Protein Function

In the kidney, HNF1B is expressed in all tubular epithelial cells and controls the expression of different genes involved in membrane transport, cell differentiation, and metabolism. HNF1B binds DNA and modulates gene expression by inducing conformational changes in chromatin structure via its interaction with coactivators and corepressors [216]. HNF1B is widely expressed in the embryonic kidney and is required at multiple steps of kidney development and signaling, and it is essential in branching morphogenesis, nephrogenesis, nephron patterning, and tubulogenesis. Mice with deletion of both *Hnf1b* alleles do not survive postnatally whereas kidney-specific inactivation of *Hnf1b* causes a variant of polycystic kidney disease [69, 217]. *Hnf1b* null mice have pronounced tubular developmental defects, including an absence of proximal, distal, and loop of Henle segments [218]. As a consequence, *HNF1B*-mutant kidneys are hypoplastic with impaired tubular development [219]. Moreover, preclinical studies have shown that HNF1B downregulates cystic kidney disease genes, including *UMOD*, *PKHD1*, and *PKD2*, which explains cyst formation in mutant animals [216, 217, 219]. In the adult kidney, HNF1B controls the expression of genes required for intrarenal metabolism and solute transport by tubular epithelial cells, providing support to the observed phenotype of distal tubular impairment in adult patients with *HNF1B* mutations [46]. Furthermore, HNF1B has apparent roles in epithelial–mesenchymal transition (EMT), Wnt signaling, renal cell fibrosis (through the *TWIST2*-

dependent transcriptional network), and aberrant TGF-β signaling, all of which link mutations in HNF1B with ADTKD [220].

Clinical Presentation

Heterozygous mutations of *HNF1B* are among the most common single-gene mutations found in developmental kidney disease [21]. This condition is often undiagnosed due to its heterogeneous clinical manifestations (Table 3), incomplete gene penetrance, and frequently arising from de novo mutations with no family history of disease [11, 24, 26–28]. De novo mutations occur in approximately 40% of patients, while the remaining affected patients follow a dominant inheritance pattern [221–223]. In humans, *HNF1B* mutations cause congenital abnormalities of the kidney and urinary tract (CAKUT), including renal agenesis/hypoplasia, multicystic dysplastic kidneys (Fig. 5), horseshoe kidneys, and glomerulocystic kidney disease (Fig. 6) [11, 28, 224]. *HNF1B* mutations can also cause ADTKD, often associated with hyperuricemia, hypomagnesemia, hypokalemia, diabetes mellitus, and Müllerian duct abnormalities [27, 220].

Clinically, disease manifestation varies with age. In adults, *HNF1B* mutations cause MODY type 5, which is an early-onset (commonly before 25 years of age) autosomal dominant, non-autoimmune form of diabetes mellitus; these individuals are neither obese nor insulin-dependent and may present with bilateral polycystic kidney disease without proteinuria [30, 223]. In contrast, children carrying *HNF1B* mutations have kidney disease that dominates the clinical picture including CAKUT, ARPKD, and/or early CKD [27, 28, 75]. Moreover, a 1.5 MB microdeletion on chromosome 17q12 which includes *HNF1B* and 14 other genes can cause a wide range of extrarenal clinical features such as hypomagnesemia, genital abnormalities (that may become more evident with age), autism spectrum disorders, attention-deficit/hyperactivity disorder, and facial dysmorphism [43, 225–228]. These extrarenal manifestations should trigger suspicion for *HNF1B* mutations and unrecognized abnormalities of the kidneys and the urinary tract [45]. It appears that the risk for severe CKD is lower in

Table 3 Kidney and extrarenal manifestations of patients with *HNF1B* gene mutations[a]

Organ	Comments
Kidney Bilateral hyperechogenic kidneys Bilateral cysts Glomerulocystic disease Multicystic dysplastic kidney Single kidney Horseshoe kidney Oligomeganephronia Hydronephrosis and megaureter Chronic kidney disease Hypomagnesemia Hypokalemia Chromophobe renal carcinoma (exceptional)	Most frequent cause of kidney dysplasia of monogenic origin Normal or small-sized kidneys Amniotic fluid preserved in prenatal ultrasound Renal failure in adults, rare in children Electrolyte disorders mainly in adults
Endocrine Early-onset diabetes (MODY-5) New-onset diabetes after transplantation Pancreatic cysts Hypoplastic pancreatic body and tail	<5% of MODY-type diabetes Anticalcineuric drugs downregulate HNF1B
Digestive Pancreatic exocrine dysfunction Elevated liver enzymes (common) Neonatal cholestasis (rare)	Casual finding, most patients asymptomatic
Genital Bicornate uterus Uterus didelphys Double vagina Vaginal hypoplasia and absent uterus Cryptorchidism Hypospadias Epididymal cysts Agenesis of the vas deferens	Mayer-Rokitansky-Küster-Hauser syndrome cases in HNF1B deletions
Others Early-onset gout (hyperuricemia)	Gout precedes chronic kidney disease
Development-psycho Epilepsy Autism spectrum disorder Developmental delay	Associated with 17q12 rearrangement

[a] Modified from [2] and [225]

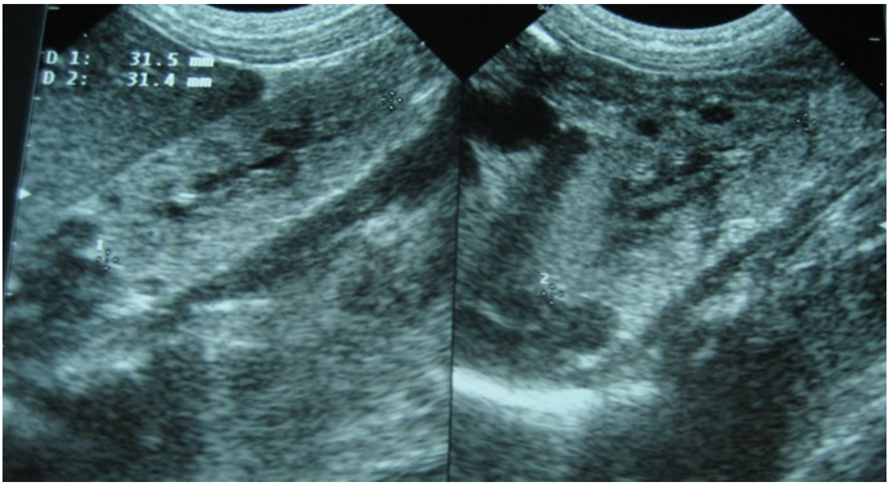

Fig. 5 **Renal ultrasound images from a patient with *HNF1B* mutation**. Renal ultrasound shows bilateral hyperechogenic, cystic, and small kidneys (right kidney length 31.5 mm on the right, and left kidney length 31.4 mm on the left) in a child with a complete *HNF1B* gene deletion

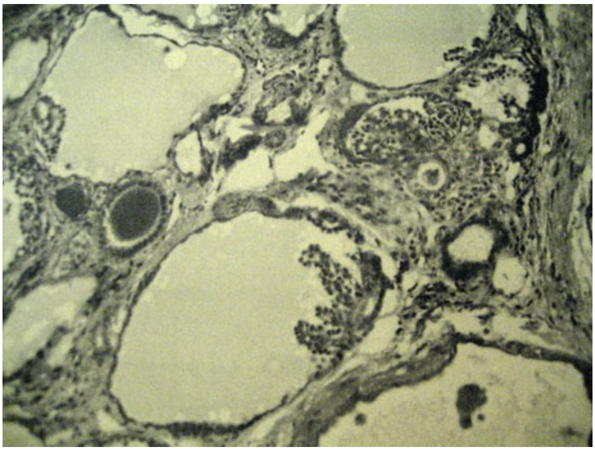

Fig. 6 **Histological image from a patient with *HNF1B* mutation**. Kidney histology of the same patient as in Fig. 5 with a complete *HNF1B* gene deletion shows glomerulocystic disease

patients with *HNF1B* deletions compared to patients with *HNF1B* point mutations, raising the possibility of a dominant negative effect of a mutant protein in the latter [229]. However, both, truncating *HNF1B* mutations and *HNF1B* deletions, can cause tubulointerstitial disease in ADTKD-*HNF1B* [27, 230]. Thus, in humans, *HNF1B* mutations result in an expanded clinical spectrum [2]. Few genotype-phenotype correlations have been identified, in part because the severity of renal disease is highly variable even within families carrying the identical mutation with the exception of affected individuals with 17q12 deletions and developmental disorders [43, 226]. The wide phenotypic spectrum may also indicate that time-specific HNF1B activity is required during organogenesis and the involvement of other modifier genes [69, 231–233]. One-third of the reported human *HNF1B* mutations consist of whole-gene deletions that require specific diagnostic tests to be detected [27].

Pathophysiology

More than 100 pathogenic mutations of *HNF1B* have been reported in humans [27]. The mutations range from intragenic mutations, including missense, frameshift, nonsense, splice site, and small insertions or deletions, to whole-gene deletions and large genomic rearrangements. A lack of HNF1B in renal tubular cells activates the *TWIST2*-dependent transcriptional network which stimulates EMT pathways and abnormal TGF-β signaling. As a result, cells have increased expression of extracellular matrix components that leads to kidney fibrosis [220]. Additionally, HNF1B also regulates a coactivator of the transcription factor peroxisome proliferator-activated receptor-γ (PPARγ). This factor controls mitochondrial biogenesis and function, suggesting that mitochondrial defects may drive pathology in ADTKD [74, 234].

Diagnostic Testing

Mutations in *HNF1B* can be assessed by gene sequencing and testing for gene deletions. Given the high incidence of de novo *HNF1B* deletions, practitioners should test for large deletions with a multiplex ligation-dependent probe amplification (MLPA) assay, as large deletions could be missed by direct gene sequencing. In order to detect the frequently seen 17q12 deletion, a chromosomal microarray or a copy number variation analysis may be required [235].

Therapeutic Approaches

Children with ADTKD-*HNF1B* should be followed by a pediatric nephrologist [1]. Presently, only conservative management is available for ADTKD-*HNF1B*. In case of severe kidney dysplasia resulting in pulmonary hypoplasia, the prognosis can be grave and renal replacement therapy may be needed early. However, in the majority of patients, ADTKD-*HNF1B* is a slow progressive condition [230]. The clinical management should target CKD complications such as metabolic bone disease, anemia, hypertension, hypomagnesemia, hyperuricemia, and short stature as well as extrarenal manifestations such as pancreatic dysfunction and/or correction of genital tract malformations. If a 17q12 microdeletion is suspected or confirmed, psychological evaluation and therapy may be needed for autism and/or ADD [21]. After a kidney transplant, patients with ADTKD-*HNF1B* should be closely monitored for new onset diabetes mellitus after transplant (NODAT) given that tacrolimus-based immunosuppression and steroids aggravate their already higher susceptibility for diabetes [53, 236]. Moreover, tacrolimus can cause or worsen underlying hypomagnesemia in ADTKD-*HNF1B* patients, which is a known key factor for development of NODAT [54, 55, 237, 238]. Practitioners should consider immunosuppressive alternatives such as mTOR inhibitors, belatacept, and/or steroid-sparing regimens [56].

ADTKD-REN Is Caused by Mutations in the Gene Encoding Renin

ADTKD-*REN* is an infrequent cause for ADTKD with only 30 families reported to date [22]. The gene encoding renin (*REN*) is located on chromosome 1q32.1 and encodes preprorenin which is selectively synthesized in the juxtaglomerular apparatus [239]. Preprorenin contains a 23 amino acid N-terminal signal peptide, a 43 amino acid prosegment, and a 340 amino acid mature renin peptide [239]. During renin synthesis, the signal peptide is crucial for trafficking of the nascent preprorenin into the ER lumen (Fig. 7). Inside the ER, preprorenin undergoes further processing to prorenin and glycosylation. Prorenin is then proteolytically processed to the mature endopeptidase renin (Fig. 7) [240]. Prorenin binds its receptor and modifies a variety of signaling pathways [241]. Renin converts angiotensinogen to angiotensin 1, an aspartic protease which thereby stimulates angiotensin and aldosterone action.

Protein Function

As an activator of the Renin-Angiotensin-Aldosterone system (RAAS), renin has different roles in the kidney including renal development, blood pressure regulation, modification of erythropoiesis, and thirst regulation [2]. Stimulators of renin synthesis are hypotension (baroreceptor reflex) and decreased chloride delivery to the macula densa [242, 243]. The significance of renin for renal development was confirmed by patients with compound heterozygous or homozygous mutations in *REN* who develop renal tubular dysgenesis (OMIM 267430) [244]. Fig. 7 Wildtype and mutant renin trafficking. (**a**) Wild-type preprorenin translocates in the ER. During translocation, the signal peptide is cleaved, leaving prorenin, which is glycosylated. After the translocation of prorenin through the ER-Golgi Intermediate Compartment (ERGIC), prorenin is cleaved to renin which can be secreted. (**b**) Mutations in the signal peptide interfere with the translocation of the peptide across the ER membrane, leading to abnormal preprorenin location in the cytoplasm. When mutations are located in mature renin, the altered protein is retained in the ER causing ER stress. Mutations in the prosegment result in conformational changes which interfere with protein synthesis, protein folding, and trafficking leading to impaired protein secretion, renin deficiency, and cellular toxicity. This figure was published in [22]

frequently display fetal or perinatal lethality due to renal failure and pulmonary hypoplasia [245]. This condition resembles the fetopathy caused by maternal use of angiotensin II receptor blockers or angiotensin converting enzymes inhibitors (ACEi) during pregnancy [246, 247].

RAAS likely influences erythropoiesis mostly through angiotensin II (Ang II). Ang II type 1 receptors have been identified on the surface of erythroid progenitor cells [248]. Treatment of cultured erythroid progenitor cells with Ang II increased blood forming units, an effect that was prevented by cotreatment with losartan [248]. Ang II is also considered a secretagogue for erythropoietin. Patients with renin-mediated hypertension have higher erythropoietin levels compared to patients with nonrenin-mediated hypertension [249, 250]. One means by which the RAAS affects erythropoietin appears to be from Ang II-mediated vasoconstriction of renal vessels and reduction of postglomerular peritubular blood flow which subsequently decreases oxygen delivery to the renal tubulointerstitium [251, 252]. Ang II also directly interacts with hypoxia inducible factor 1 (HIF-1) which is a key regulator in erythropoiesis [253]. Prepubertal ADTKD-*REN* patients respond well to erythropoietin treatment, although these treatments are usually unnecessary after puberty due to enhanced production of sexual steroids [12, 254] .

Clinical Presentation

ADTKD-*REN* typically presents with early onset of anemia (often in the first year of life), hyperuricemia, and gradually worsening CKD [12, 22, 255–257]. Most patients present before the age of 10 years. The kidney disease progresses with histology that includes tubular atrophy, glomerular scarring, and interstitial fibrosis. Staining for prorenin and renin shows less signal in the granular cells of the juxta-glomerular apparatus and no staining in tubular epithelia [12, 255]. The symptoms and signs of disease depend on the location of the *REN* mutation. Signal peptide mutations are the most common (62% in cohort of 111 affected individuals) and present mostly between childhood and adolescence (mean age at presentation of 19.7 years) with anemia (31% of patients), gout (25%), CKD (22%), and/or AKI (10%) [22]. Prosegment mutations were found in 24% of the aforementioned cohort with most patients presenting before the age of 10 years (61% of this group) with anemia (in 50%) and gout (in 36%). Mutations in the mature protein were the least common with 14% in the aforementioned cohort and were associated with the latest mean age of presentation (37 years) with gout (in 75%) and CKD (in 25%) [22]. Age of onset of ESKD varied between the three different mutation sites from 53 years (signal peptide), to 50.8 (prosegment) to 63.6 years (mature protein). Anemia was described in 91% of ADTKD-*REN* patients in childhood and is associated with a low serum erythropoietin [12, 22]. The anemia in patients with ADTKD-*REN* is reminiscent of anemia seen in patients treated chronically with ACEi or ARBs as the RAAS stimulates erythropoietin synthesis [258, 259]. The anemia in ADTKD-*REN* often resolves during puberty, most likely due to the higher synthesis of sexual hormones and their ability to stimulate erythropoietin production [12]. Other typical features of ADTKD-*REN* include hyperkalemia and mild hypotension which are both caused by the impaired activation of the RAAS. The severity of hyperkalemia usually does not correlate to the degree of renal function decline in patients [12]. Some patients are polyuric and many have gout and hyperuricemia [2].

Pathophysiology

Heterozygous mutations in *REN* lead to apoptosis in renin-producing cells due to intracellular accumulation of abnormal renin protein [12, 22]. While homozygous *REN* mutations are highly lethal due to abnormal kidney development resulting in renal tubular dysgenesis, heterozygous *REN* mutations appear to not overtly perturb kidney development. Heterozygous *REN* mutations of the signal peptide result in impaired ER translocation and processing of Preprorenin, which results in a lower secretion of prorenin and renin. Similar to ADTKD-*UMOD*, cell lines that express a signal peptide mutation of REN had increased ER stress [12].

Diagnostic Testing

One should consider and test for a *REN* mutation if a prepubertal patient has anemia and/or hyperkalemia which is worse than expected based on the degree of CKD [12, 255–257]. Erythropoietin, renin, and aldosterone levels may be reduced, and reticulocyte count may be low. Hyperuricemia is commonly found in ADTKD-*REN* [12]. Immunohistochemical staining of kidney tissue may show reduced staining for renin in the juxtaglomerular apparatus in patients with ADTKD-*REN* [12, 255].

Therapeutic Approaches

Patients may be more susceptible to hypotension and acute kidney injury due to volume contraction. Therefore, patients should be counseled to avoid nonsteroidal anti-inflammatory drugs. Given the tendency for hypotension, the use of ACEi or ARBs may be impractical. If using the aforementioned drugs, patients and families should be instructed to not give them if the patients become dehydrated. Fludrocortisone may be used to improve hypotension and hyperkalemia in these patients [255]. Younger patients may require erythropoietin therapy. CKD slowly worsens over time, and renal replacement therapy may be required, often between 30 and 80 years of age [22].

ADTKD-SEC61A Is Caused by Mutations in SEC61A

After excluding mutations for all known ADTKD-causing genes in two affected family pedigrees, Bolar et al. performed additional genetic analysis including linkage studies and whole-exome sequencing; ultimately, the group identified heterozygous *SEC61A1* mutations as a novel and rare cause of ADTKD [13]. The *SEC61A1* gene is located on chromosome 3q21.3 [13]. In addition to gout, ADTKD-*SEC61A* patients have extrarenal symptoms such as anemia, neutropenia with multiple skin infections, intrauterine growth retardation, cleft palate, and polydactyly.

Protein Function

The *SEC61A1* gene encodes the protein transport protein SEC61 subunit alpha isoform 1 (SEC61α) which assembles with SEC61 subunit beta (SEC61β) and SEC61 subunit gamma (SEC61γ) to form the heterotrimeric protein-conducting channel SEC61 which is a part of the mammalian ER translocon [13]. The SEC61 complex is required to transport newly synthesized secretory proteins into the ER, integrate nascent proteins into membranes, and maintain ER ion permeability barrier. Thus, the human SEC61 complex has a role in translocation of proteins from the cytosol into the ER, and in retrograde transport of multidomain integral membrane proteins from the ER to the cytosol for proteasomal degradation.

Clinical Presentation

Bolar et al. described two unrelated families with ADTKD and congenital anemia (a three-generation family in Belgium, with 7 affected members out of 18 studied, and a family in the United States, with 2 affected individuals out of a pedigree of 8) [13]. In the first family, the clinical phenotype was characterized by autosomal dominant progressive CKD associated with congenital anemia and intrauterine and postnatal growth retardation. Other variable findings included cleft palate, bifid uvula, velopharyngeal insufficiency, preaxial polydactyly, and mild cognitive impairment. Affected individuals exhibited normal blood pressure, normochromic, normocytic anemia responsive to erythropoietin, elevated serum creatinine levels, and mild hyperuricemia, without proteinuria [13]. Renin and aldosterone concentrations were in the lower range. Fractional excretion of sodium and uric acid was low. Ultrasound images demonstrated small, dysplastic kidneys without cysts. Kidney biopsies revealed multiple small foci of tubulo-interstitial lesions and glomerulocystic changes. In the second family, the major clinical findings were congenital anemia and neutropenia, gout in the second decade of life, repeated cutaneous abscesses, and CKD. In the second family, affected members had normal linear growth and intelligence. Renal ultrasound images demonstrated normal-sized kidneys with multiple bilateral simple cysts [13]. In addition to causing kidney disease, *SEC61A1*-pathogenic variants have been shown to cause monogenic plasma cell deficiency in patients [13, 260, 261].

Pathophysiology

SEC61A1 mutations interfere with the function of the translocon pore by affecting the integrity of the plug domain/constriction ring of the translocon pore. These conformational changes result in the accumulation of mutated SEC61α protein in the ER. Moreover, the kidney biopsy of an ADTKD-*SEC61A1* patient showed mislocalized mutant SEC61α protein in the Golgi apparatus and the ER-Golgi intermediate compartment (ERGIC) (similar to ADTKD-*REN*) (Fig. 7) [13]. The detection of mutant SEC61α in the Golgi and ERGIC suggests that the mutant protein is identified by the cell as abnormal and eventually degraded in the ER. It is thought that destabilizing the translocon pore may lead to pathological post-translational modifications, conformational changes, and forward trafficking of secretory and transmembrane proteins that include UMOD, MUC1, and REN. Additional studies in zebrafish embryos confirmed that *sec61al2* variants induced convolution defects in pronephric tubules [13]. Together, these data are consistent with a crucial role of *SEC61A1* for proper tubular organization [13]. Other effects of *SEC61α* mutations include abnormal cellular Ca^{2+} homeostasis and energy metabolism [262]. The impaired functions of the translocon are speculated to either cause or impair the cell to compensate appropriately for ER stress, leading to apoptosis and tissue damage. As noted, chronic ER stress is a major pathogenic mechanism driving development and progression of ADTKD caused by *UMOD*, *MUC1*, and *REN* mutations [7, 10, 12, 171]. Patients with ADTKD-*SEC61α* may have a common pathogenetic mechanism leading to similar clinical symptoms as those with the other types of ADTKD [2].

Diagnostic Testing

Due to the limited number of patients, no specific tests for ADTKD-*SEC61A1* exists, except direct sequencing for *SEC61A1* mutations. Gout and extrarenal symptoms are often present, as noted above. Slowly progressive CKD is a typical feature. Complete blood counts may show anemia and neutropenia. Kidney biopsies may show glomerulocystic changes in addition to tubulointerstitial fibrosis. Urinary UMOD may also be reduced in ADTKD-*SEC61A1* patients.

Therapeutic Approaches

The anemia associated with ADTKD-*SEC61A1* responds well to erythropoietin. Fludrocortisone may be effective for patients with hyperkalemia due to low renin and aldosterone concentrations. Other manifestations of CKD should be treated as per common guidelines.

Treatment of ADTKD

Presently, no specific treatments or recommendations exists for most patients with ADTKD, in part from a lack of published trials. Patients with mild and moderate CKD due to ADTKD should undergo annual follow-up clinic visits. In asymptomatic children of ADTKD patients, laboratory studies may be performed dependent on family preference. Most often, CKD in children affected by ADTKD-*UMOD* or ADTKD-*MUC1* is mild and may not require significant therapy. In contrast, children with *HNF1B* and *REN* mutations may require more intensive early interventions. There are no data on whether angiotensin-converting enzyme inhibitors or angiotensin blockers improve outcomes in ADTKD patients. Given these medications are widely used in pediatric CKD cohorts and generally tolerated well, some advocate attempting treatment with these medications [263, 264]. If these medications are used, losartan may be a good choice in hyperuricemic patients as it lowers uric acid levels due to increased urinary urate excretion [265, 266]. In patients with gout or hyperuricemia, allopurinol or febuxostat may help to prevent future episodes of gout [24, 37]. It remains unclear if allopurinol reduces CKD progression in ADTKD. In a cohort of adult patients with CKD stages 3 and 4, allopurinol did not attenuate in the decline of GFR [267]. Additionally, allopurinol may exacerbate gout and rarely causes severe allergic reactions. As such, allopurinol should be immediately discontinued in cases of rash, which is suspicious for allergy. Allopurinol should also be avoided in pregnancy as it can cause cleft palate and other facial anomalies in the fetus. Diuretics should be used carefully as they may worsen volume depletion, hyperuricemia, and gout [268]. Generous water intake may be helpful to compensate for urinary concentration defects. Low salt intake is typically not recommended in children with CKD as that may aggravate hyperuricemia and volume depletion in ADTKD-*UMOD* and ADTKD-*REN*. As in all forms of CKD, nonsteroidal anti-inflammatory drugs should be avoided in ADTKD patients, especially ADTKD-*REN* patients that appear to be very susceptible to acute kidney injury from these medications [1]. As in other forms of CKD, management should include control of blood pressure, lifestyle modifications, and treatment of hyperuricemia, anemia, metabolic acidosis, bone disease, electrolyte abnormalities, and cardiovascular disease. Anemia due to ADTKD-*REN* and in all other more advanced stages of CKD from other ADTKD forms is amenable to erythropoietin therapy. In patients with ADTKD-*REN*, fludrocortisone may improve hypotension and hyperkalemia. That said, practitioners need to balance the potentially beneficial effects of fludrocortisone against possible risks of mineralocorticoid-induced aggravation of interstitial fibrosis. As such, fludrocortisone should be avoided in patients with severely declining kidney function, hypertension, or edema. Possible future treatment options for ADTKD may include small biological molecules. For example, ADTKD-*MUC1* human-iPCS-derived kidney organoids and kidneys from heterozygous MUC1-fs knockin-mice had markedly reduced MUC1-fs accumulation when treated with the small molecule BRD4780 [57]. Presently, dialysis and/or kidney transplantation still remain the only treatment for ESKD due to ADTKD. To date, no cases of recurrent ADTKD has been reported in the allografts [269]. ADTKD-*HNF1B* patients with diabetes mellitus may require combined kidney/ pancreas transplantation.

Conclusion

ADTKD is a relatively newly characterized group of tubulointerstitial nephropathies which frequently result in the accumulation of a misfolded, mutant protein in the renal tubular cells. The causative mutated genes encode the aberrant protein that accumulates (e.g., UMOD, MUC1, or REN), encode proteins required for other protein processing in the ER (e.g., SEC61A1), or encode factors required for proper expression of other target genes (e.g., *HNF1B* regulation of UMOD expression). Often, accumulation of aberrant proteins with ADTKT leads to ER stress and ADTKD. Similarly, *DNAJB11* mutations result in an ADPKD-ADTKD phenotype that appears secondary to ER stress, as DNAJB11 is a key chaperone that participates in ER quality control [71]. Most of the ADTKD forms can present in childhood but typically do not lead to ESKD until adulthood. As clinicians and researchers have become more aware of ADTKD, it is now recognized as a major cause of monogenic kidney disease [1]. A challenge in making the correct diagnosis is the lack of specific symptoms. In addition, ADTKD poses an ethical dilemma as to whether the practitioner should assess for causative mutations as there are no specific therapies at present. Quality of life is rarely affected in children with ADTKD unless they have gout, diabetes, hypomagnesemia, neuropsychological symptoms, or anemia. Better biomarkers may help in making the correct diagnosis in the future. International registries and ongoing preclinical studies will hopefully help to identify better therapeutic options. Promising therapies include the small molecule BRD4780, which may become a targeted therapy for ADTKD-*MUC1*. Other future treatments could include the use of antisense oligonucleotides to reduce the production of mutant proteins (as happens with *UMOD*, *MUC1*, and *REN* mutations), chemical chaperones to aid with secretion of mutant proteins, inhibition of inflammatory TNF signaling, and/or proteostasis modulators [2]. As targeted therapies become available, pediatric nephrologists may be critical in initiating early treatment to remove mutant proteins from renal tubular cells before permanent damage has happened [270].

Abstract

A significant increase in the frequency of childhood urinary stone disease has been observed during the last two decades. A recent study observed an increase in the incidence of symptomatic kidney stones from 7.9 per 100,000 children in 1996 to 18.5 per 100,000 in 2007. The highest incidence was observed in females aged 14–17 years. These findings have been replicated by others. The reason for this increase is not clear though many hypotheses have been proposed. Most affected children have idiopathic calcium stone disease while monogenic disorders, sometimes associated with chronic kidney disease, likely account for approximately 10% of pediatric kidney stone cases. Both environmental and hereditary factors significantly contribute to the risk of stone formation. All children with urinary stone diseases deserve a meticulous risk factor evaluation which forms the basis for individualized and targeted treatment of the underlying disorders.

Epidemiology of Childhood Urinary Stone Disease

Urinary stone disease is a common health problem in all parts of the world with an estimated lifetime prevalence of approximately 10–12% in men and 5–6% in women [1, 2]. Although the epidemiology of childhood urinary stone disease is less well defined than in adults, three recent population-based studies [3–5] have suggested a significant increase in the frequency of pediatric urolithiasis over the past few decades. A study conducted in the state of South Carolina [3] found an overall increase in the incidence of symptomatic kidney stones in children <18 years of age, from 7.9 per 100,000 children in 1996 to 18.5 per 100,000 in 2007. In that study the highest incidence increase was in females aged 14–18 years, followed by girls aged 9–13 years. Overall, the risk of developing stone events was 10 times greater in children aged 14–18 years than for those 0–3 years of age [3]. A significant increase in the incidence of childhood urinary stones was also observed in a recent population-based study from Iceland [5]. The total annual incidence increased from 3.7/100,000 in the years 1985–1989 to 11.0/100,000 in the years 1995–2004 and then decreased to 8.7/100,000 in 2010–2013. The incidence rise was highest in girls aged 13–17 years, in whom it increased from 9.8/100,000 in 1985–1989 to 39.2/100,000 in 2010–2013. Findings were similar in the third study [4] that was based on the Rochester Epidemiology Project [4]. In all three studies, the incidence over time did not change significantly in prepubertal children [3–5].

Published data on childhood kidney stone recurrence are limited. A retrospective population-based study of 190 Icelandic individuals who had their first stone at the age of <18 years, showed a recurrence rate of 26%, 35%, and 46% at 5, 10, and 20 years, respectively [6]. Stone recurrence was not affected by sex or age at first stone diagnosis. A retrospective single-center investigation on US children aged 3–18 years documented stone recurrence in approximately 50% of cases at 3 years [7]. Based on these data, the rate of stone recurrence appears to be similar in children and adults.

Multiple studies of urinary stone disease in both children [5, 8, 9] and adults [1, 10] have shown male preponderance. Recent pediatric studies have, however, found kidney stone disease to be more common in girls [3, 5, 11, 12], particularly in the age group of 10–17 years [3, 5, 13]. Conversely, recent studies have suggested a decrease in male predominance in young adults [10, 14, 15]. Taken together, these data suggest that the recently reported female predominance in childhood stone disease may be antedating a shift in the sex ratio in adults.

The reasons for the increased incidence of pediatric urinary stone disease are not clear and may include increased intake of sodium and fructose, decrease in the intake of calcium and water, and increased use of antibiotics [16]. While obesity has been shown to be a risk factor for adults [17, 18], epidemiological data in children and adolescents do not suggest a link between higher body mass index (BMI) and stone formation [16, 19]; some studies have even observed a significant association between low body weight and kidney stone formation in US children [16].

Since the higher risk of stone formation in obese adults is, at least in part, mediated by lower urine pH, higher urine pH observed in children could protect against obesity-induced urolithiasis in young subjects [20].

Several studies have shown an inverse relationship between dietary calcium intake and the risk of symptomatic kidney stones in adults [21–23]. A low calcium diet in adults increases urinary oxalate excretion, while a diet containing normal amounts of calcium and reduced amounts of animal proteins and sodium decreases urinary oxalate excretion and the risk of developing symptomatic kidney stones [24]. Dietary calcium is thought to decrease intestinal oxalate absorption by binding free oxalate [25].

Low fluid intake is a clear risk factor for nephrolithiasis [23]; US children drink on average less than before, which may contribute to the observed rise in the incidence of urolithiasis in this population [26]. Low fluid intake and increased environmental heat increase urinary supersaturation and the risk of urinary stone formation [27, 28]. Conversely, increased fluid intake reduces stone recurrence [29–31].

Finally, stone formation may be associated with antibiotic use through disruption of the normal microbiome [32]. For example, *Oxalobacter formigenes* is an intestinal bacteria that that relies on oxalate degradation to meet most of its energy and carbon needs [33]. Reduced *Oxalobacter* gut colonization due to antibiotic use may increase the bioavailability of oxalate for intestinal absorption, and consequently urinary oxalate excretion. Antibiotic use may not, however, account for the increasing incidence of urinary stone disease in children in the U.S. as recent epidemiologic data show decreasing use of antibiotics in American children [34, 35].

The prevalence of kidney stones varies between ethnic groups and geographical areas [36]. The prevalence of kidney stones in adults has been reported to be 1–5% in Asia, 5–9% in Europe, 13% in North America, and 20% in Saudi Arabia [37]. In Western industrialized nations, kidney stones are most common in non-Hispanic Caucasians, while the lowest risk is observed in African Americans [1, 36]. Similar differences between ethnic groups have also been observed in pediatric studies [3, 12, 38]. A considerable regional variability exists in stone prevalence in North America with the highest reported probability of stone formation in the South and the lowest in the West [1]. However, a recent retrospective study of nearly 4,000 hospital admissions for urinary stone disease in pediatric patients found stone hospitalizations to be more frequent in the North and Central US, compared to the Southern states [12]. Similar to adult data, stone events during summer months are associated with an increased risk of hospitalization in children [12].

Children and adolescents in Western countries predominantly form calcium stones. In a recent large US study, 89% of the stones contained calcium salts [39]. The study, which is the largest one reported to date, included 5,245 first kidney stones formed by children aged 1–17 years and analyzed between 2000 and 2009. Calcium oxalate and magnesium ammonium phosphate (struvite) were found significantly more often in females than in males (86% vs. 79% and 4.8% vs. 3.8%, respectively); uric acid stones were more commonly seen in males than in females (1.4% vs. 0.6%). The percentage of calcium oxalate stones increased with age, while stones containing calcium phosphate were more common in young children, possibly because of higher urine pH in this age group. Struvite and ammonium acid urate containing stones decreased with age. Calcium was found in 89% of the stones, calcium oxalate in 83%, calcium phosphate in 61%, and struvite in 4.4%. Other less frequently observed components were ammonium acid urate (2.8%), cystine (2.3%), uric acid (0.9%), and calcium carbonate (0.4%). The relative prevalence of the different stone types may also be changing. A single center study analyzing urinary stone composition in 179 children found a significantly higher proportion of calcium phosphate stones (60% vs. 47%) in the years 2001–2010, compared to the years 1992–2000 [40].

Finally, stone composition in developing countries including India, Pakistan, and in Southeast Asia and the Middle East, where urolithiasis is endemic, is different from that in the Western world [41, 42]. Calculi are more commonly observed in the bladder and are predominantly composed of ammonium acid urate, which is associated with the excretion of high urinary acid load caused by rice- or cereal-based diet and frequent episodes of dehydration, combined with low dietary phosphate, which reduces urinary phosphate excretion [43]. The association between stone types and various clinical conditions is illustrated in Table 1.

Nephrocalcinosis

The term “nephrocalcinosis” (Fig. 1) indicates a diffuse deposition of calcium oxalate or calcium phosphate in renal tubules and/or in the renal interstitium [45]. Compared to urinary stone disease, the pathophysiology of nephrocalcinosis is less well defined, and involves, at least in part, increased urinary excretion of calcium, oxalate, phosphate, and/or reduced excretion of citrate [45]. Nephrocalcinosis can cause renal parenchymal inflammation and fibrosis, which may lead to chronic kidney disease (CKD) [46]. It is a prominent feature of conditions that cause hypercalciuria, such as primary hyperparathyroidism, genetic tubular diseases, and chronic use of loop diuretic use (especially in infants) and conditions causing hyperoxaluria, including excessive vitamin C intake or ethylene glycol ingestion [47–50].

While most urinary stones form in otherwise healthy people, nephrocalcinosis is usually caused by an underlying disorder [51] that requires a thorough evaluation, including metabolic and genetic studies. The severity of nephrocalcinosis is difficult to evaluate. Grading systems, based on ultrasound imaging, have been proposed, but are not routinely used in the clinical setting [52].

Increased risk of nephrocalcinosis has been observed in preterm infants [44, 51]. Earlier studies reported renal calcifications in 16–64% of very low and extremely low birth weight infants or premature babies of less than 32 weeks’ gestation but more recent studies suggest lower prevalence rates (7–41%) [48]. The risk of renal calcifications in small infants is associated with the use of drugs (in particular furosemide), vitamins, electrolyte supplementation, metabolic acidosis, longer duration of mechanical ventilation, and parenteral nutrition [44, 48, 51]. Furosemide, steroids, methylxanthines, vitamin D, and supplementation with

Fig. 1 Renal ultrasound examination. (**a**) Nephrocalcinosis in a 6-year-old boy with distal renal tubular acidosis. (**b**) An 8 mm shadowing (short arrow) stone (long arrow) in the right kidney of a 12-year-old boy with recurrent stone disease

calcium and sodium increase renal calcium excretion and may cause hypocitraturia in very low birth weight infants [51]. Risk factors for hyperoxaluria in premature children include parenteral nutrition and enteral feeding with formula, as opposed to breast milk [48]. A positive family history of urinary stone disease, male gender, and white race also increase the risk of nephrocalcinosis in preterm infants [51]. Kidney stones are not observed more frequently in former preterm infants, even in those with a history of severe nephrocalcinosis during the neonatal period [48, 53]. Spontaneous resolution of nephrocalcinosis may occur during the first years of life [48]. Long-term follow-up ultrasound studies of preterm neonates have shown the persistence of nephrocalcinosis in 34%, 15%, and 10% of children after 1.3, 2.5, and 7.4 ± 1.0 years, respectively [48, 53].

Transient renal medullary hyperechogenicity in neonates, mimicking nephrocalcinosis, is a benign condition caused by Tamm Horsfall/Uromodulin tubular precipitations which typically resolves within a few weeks [54].

Risk Factors for Urinary Stone Disease

Urine metabolic risk factors for calcium kidney stones in the absence of systemic diseases include idiopathic hypercalciuria, hyperoxaluria, hypocitraturia, low urine volume, and hyperuricosuria [19, 55, 56]. These factors have been reported in 40–95% of first time pediatric stone formers [11, 57, 58]. Table 2 shows normal values for urinary solute excretion in children <18 years of age, and metabolic abnormalities associated with urolithiasis are listed in Table 3.

Idiopathic Hypercalciuria

Idiopathic hypercalciuria is defined as the renal overexcretion of calcium, despite normal serum calcium levels, and in the absence of an underlying cause (Table 2) [63]. It is the most common risk factor for urinary stone disease, which is observed in 50–80% of pediatric kidney stone patients [11, 64]. A recent carefully designed study by Bergsland et al. [19] found that hypercalciuria is the principal risk factor for calcium stone formation in children; in the same study the frequency of other risk factors for stone formation, such as hyperoxaluria, hypocitraturia, abnormal urine pH, or low urine volume, were similar between stone formers and controls. The mechanisms of idiopathic hypercalciuria include [1] primary (not vitamin D-mediated) increase in intestinal calcium absorption (type 1 absorptive hypercalciuria) or excess of 1,25-$(OH)_2D3$-mediated calcium absorption (type II absorptive hypercalciuria); [2] decreased renal calcium reabsorption (renal hypercalciuria) or decreased renal phosphorus reabsorption (type III absorptive hypercalciuria), and/or [3] enhanced bone resorption (resorptive hypercalciuria) [65]. Bone mineral density is reduced in individuals with idiopathic hypercalciuria; a large cross-sectional study from the Third National Health and Nutrition Examination Survey (NHANES III) showed that male subjects with history of kidney stones had lower femoral neck bone mineral density and higher fracture risk than control subjects [66]. An inverse linear correlation between age and bone mineral content has been observed in children with idiopathic hypercalciuria suggesting that osteoporosis may start in childhood [67].

Dietary factors affecting urine calcium excretion include the intake of animal protein, sodium, potassium, phosphorous, and calcium [65]. A direct association has been established between animal protein ingestion and the risk of kidney stone formation in adults in large prospective cohort studies [21, 23] and clinical trials [68, 69]. Animal protein ingestion produces an acid load, which may promote skeletal calcium losses and hypercalciuria [70–72]. High sodium intake increases urinary calcium excretion [73] by inhibiting tubular calcium reabsorption [65]. Conversely, low sodium intake decreases urinary calcium excretion [74]. Dietary potassium has an opposite effect on urinary calcium excretion; the primary sources of potassium are the organic anion salts of fruits and vegetables, which increase the oral alkali intake, and reduce the net acid excretion [65]. Low dietary phosphorous and increased renal

phosphate leak stimulate the activation of vitamin D, which increases intestinal calcium absorption and urinary calcium excretion, promoting calcium stone formation [65]. Finally, a markedly increased dietary calcium intake can cause hypercalciuria. Studies have documented a strong genetic component to idiopathic hypercalciuria, which is transmitted as a complex trait [75].

Hyperoxaluria

Hyperoxaluria has been reported in 4–40% of childhood stone formers [11, 76–78] (Tables 2 and 3). Hyperoxaluria can be caused by increased dietary intake (dietary hyperoxaluria), over-absorption of oxalate in patients with fat malabsorption (enteric hyperoxaluria), and inherited

enzyme deficiencies [46, 55, 70]. Oxalate is an end product of metabolism that is eliminated by the kidneys [79]; even moderate changes in urinary oxalate excretion can significantly increase calcium oxalate supersaturation, promoting stone formation [79]. A substantial proportion of urinary oxalate is produced by the endogenous metabolism of glycine, glycolate, hydroxyproline, and by the metabolic degradation of dietary ascorbic acid [23]. Excessive dietary oxalate intake (rhubarb, spinach, celery, dark roughage, chocolate, cocoa, coffee and tea) also increases the urinary oxalate load [80] and the risk of calcium oxalate stone formation [81]. Dietary oxalate restriction in adult kidney stone formers with mild hyperoxaluria has been shown to decrease renal oxalate excretion by 35% [82]. In addition, intestinal oxalate absorption varies inversely to dietary calcium intake; calcium-poor diets promote intestinal oxalate absorption and hyperoxaluria [42]. By a similar mechanism, malabsorbed fatty acids in enteric hyperoxaluria bind intestinal calcium, increasing oxalate absorption [83]. Inflammatory bowel disease [84], celiac disease, cystic fibrosis (CF), other forms of exocrine pancreatic insufficiency, diseases of the biliary tract, and short bowel syndrome, are conditions associated with enteric hyperoxaluria [42].

Overall, 5–10% of patients with CF develop calcium oxalate stones [44]. In addition to hyperoxaluria [44, 85] secondary to pancreatic insufficiency, patients with CF often have reduced intestinal colonization with oxalate-degrading bacteria [44, 85] and hypocitraturia [85].

Bariatric surgery is a risk factor for kidney stone formation [86] that is primarily caused by malabsorptive enteric hyperoxaluria, and may lead to CKD [87, 88].

Hypocitraturia

Urinary citrate is a small molecular inhibitor of kidney stone formation [89]. Hypocitraturia has been reported in 15–70% of pediatric stone formers in various countries (Table 2) [11, 76, 78, 89]. Decreased citrate excretion may occur as an isolated abnormality or can be associated with other risk factors for stone formation. Citrate binds free urinary calcium, lowering calcium supersaturation [90] and augments the inhibitory effect of Tamm-Horsfall protein on calcium oxalate crystallization [91]. Hypocitraturia can be idiopathic [90] or is associated with metabolic acidosis [55, 70]. Intracellular acidosis in renal tubular cells secondary to systemic acidosis or hypokalemia increases citrate reabsorption, leading to hypocitraturia [42]. Idiopathic hypocitraturia can also be inherited [92]. Animal proteins increase the urinary acid load, which reduces urinary citrate concentration in addition to promoting skeletal calcium losses and hypercalciuria (see above) [70, 71]. In contrast, fruits and vegetables are rich in citrate, which is metabolized into carbon dioxide and water, increasing urinary pH [81].

Hyperuricosuria

Hyperuricosuria has been reported in 4–27% of pediatric stone formers [76], and is a risk factor for both calcium oxalate [93, 94] and uric acid stone formation (Table 2) [95]. High urinary uric acid concentration promotes calcium oxalate stone formation through heterogeneous nucleation [55]. Allopurinol reduces uric acid production and decreases the risk of stone formation in adults with idiopathic calcium nephrolithiasis [96].

The diagnosis of a uric acid stone in a child should always prompt physicians to look for inherited [46] or secondary causes of hyperuricosuria, including hypoxanthine-guanine phosphoribosyl-transferase (HPRT) deficiency or conditions associated with high uric acid production, such as myelo- and lymphoproliferative disorders, tumor lysis syndrome or ketogenic diet [44].

Structural Malformations of the Urinary Tract and Urinary Tract Infections

Structural malformations of the urinary tract may disrupt urine flow, and represent important risk factors for both stone formation and urinary tract infections. They have been reported in up to -one-third of pediatric stone formers [5, 11, 76]. In the past, a high proportion of urinary stones were associated with urinary tract abnormalities and infections caused by urease producing bacteria, leading to the formation of struvite stones, particularly in young boys [97]. Nowadays, infection-related urinary stones in children are becoming increasingly rare because antenatal ultrasound detects most structural urinary tract malformations, allowing early interventions that reduce the risk of infections [97]. Splitting of urea results in the production of ammonium and bicarbonate ions, which can increase urine pH to 7 or higher [98]. Alkaline pH dissociates phosphate, causing precipitation of calcium phosphate and magnesium ammonium phosphate (struvite) that aggregate on biofilms produced by bacteria. Calculi then grow rapidly with the addition of more bacteria, with the production of more matrix, and with the addition of new crystals, leading to the formation of staghorn calculi [99]. When present, struvite stones should always be completely removed because residual fragments host bacteria and serve as nidi for new stone formation [98, 100]. The eradication of infection is particularly difficult because antibiotics penetrate poorly into stones, where biofilms hosting bacteria develop [44]. At least 200 bacterial species are capable of producing urease, including *Proteus, Providentia, Haemophilus influenzea, Bordatella pertussis, Staphylococcus, Klebsiella, Pseudomonas, Enterobacter, Ureaplasma urealyticum, Corynebacterium urealyticum*, and some anaerobes [44, 98]. Struvite stones have been associated with significant morbidity including acute kidney injury (AKI), CKD, xanthogranulomatous pyelonephritis (chronic granulomatous inflammation of the kidney), and even mortality, if not properly treated [44, 98]. Since extracorporeal shockwave lithotripsy (ESWL) allows complete fragmentation and clearance of staghorn struvite calculi in less than 50% of cases [44], percutaneous nephrolithotomy is usually the method of choice for treating these stones. Treatment with acetohydroxamic acid reduces struvite stone recurrence rate; nowadays, this treatment is only prescribed if endourological treatment is not possible or when complete stone removal has not been successful [44, 98]. Patients should always be treated with antibiotics to eradicate infections; stone fragments and urine collected from the renal pelvis during surgery should be cultured before initiating a new course of antibiotics because midstream urine cultures do not always reveal the causative organism [100]. Prophylactic antibiotic treatment is frequently prescribed for 3–6 months following surgery to reduce the risk of recurrence [98]. Patients with struvite stones often have other urine metabolic risk factors for urinary stone disease [44], although their relevance is uncertain [98, 101].

Ureteropelvic junction obstruction, calyceal diverticuli, medullary sponge kidney, horseshoe kidney, ureteroceles, primary megaureter, posterior urethral valves, and bladder extrophy-epispadias complex are the congenital urinary tract disorders most commonly associated with urolithiasis [44]. Patients with spinal cord injury are at higher risk of kidney stone formation as they often have impaired bladder emptying causing recurrent urinary tract infections, and they develop hypercalciuria secondary to immobilization [44].

Drug- and Toxin-Induced Urinary Stones

Several medications and toxins can cause urinary stone formation in children and adults. Drug-induced kidney stones account for approximately 1% of calculi [102]. Stones may form by two mechanisms: (a) the stones can be directly composed of the drug or its metabolites or (b) the drug may cause metabolic abnormalities leading to the formation of calcium and less frequently, uric acid stones [102]. Examples of the first mechanism include calculi associated with protease inhibitors (indinavir, atazanavir, nelfinavir and tenovir), sulfonamides (sulfadiazine, sulfazalazine, sulfamethoxazole), antibiotics (ceftriaxone, ampicillin, amoxicillin) and antiviral agents (efavirenz), triamterene, many over-the-counter cough suppressants, expectorants (guaifenesin) or decongestants (ephedrine, pseudoephedrine), allopurinol, or silica-containing antacids; these drugs or their metabolites can crystalize in urine causing stone formation [42, 102]. Stones containing drugs are typically radiolucent and can be detected by ultrasound or non-contrast helical CT [102]. Indinavir stones can be particularly challenging to visualize [103].

Examples of drugs that induce metabolic alterations that promote stone formation include carbonic anhydrase inhibitors (acetazolamide, topiramate, zonisamide), calcium supplements, vitamin D, furosemide, or corticosteroids [41, 104]. Topiramate and other carbonic anhydrase inhibitors block proximal tubular reabsorption of sodium and bicarbonate, causing intracellular acidosis and increased citrate reabsorption, leading to urinary alkalinization, hypocitraturia, and hypercalciuria, all of which promote the formation of calcium phosphate stones [102, 105]. Uricosuric drugs increase the risk of uric acid stones, while allopurinol increases the risk of xanthine and oxypurinol stones.

Since drug-induced stones are often asymptomatic, a high index of suspicion and close monitoring of patients at-risk is necessary for timely diagnosis and treatment [104]. In the differential diagnosis of drug-induced stones, other radiolucent stones should also be considered, including 2,8-dihydroxyadenine (DHA), uric acid and, xanthine and sometimes, cystine stones. Conversely, stones secondary to treatments that modify urine composition can be distinguished from idiopathic calcium phosphate or calcium oxalate stones only with a thorough medical history.

When possible, the drugs involved should be discontinued. If alternative therapies are not available, manipulation of urine pH and volume may help preventing new stone formation or stone growth. ESWL is an effective therapy for most drug-induced stones [102].

In 2008, at least 52,000 Chinese babies were hospitalized with melamine-containing radiolucent kidney stones related to the consumption of melamine-tainted infant formula [106, 107]. Some children developed AKI secondary to urinary obstruction. After four years of follow-up kidney stones had resolved in most cases with conservative treatment only [107].

Clinical Conditions Associated with Urinary Stone Disease

Urinary stone disease is a common symptom of several inherited metabolic disorders that are detailed elsewhere in the textbook (see ▶ Chaps. 30, “The Kidney in Metabolic Syndrome,” and ▶ 38, “Renal Tubular Acidosis”) [108].

In addition, several clinical conditions increase the risk of urinary stone disease [44] and have in part been discussed in the above paragraph. They include the use of some medications, disorders that alter the acid-base equilibrium, neurological and malabsorptive conditions, prematurity, and renal parenchymal diseases, among others [44, 105]. Children with severe neurological disorders are at particularly high risk of developing urinary stones [104] because they are frequently treated with anti-epileptic drugs or with ketogenic diets, they are often immobilized [109–111], and their fluid intake may be insufficient.

Renal parenchymal disorders may be complicated with urinary infections and stones [44]. Medullary sponge kidney (MSK) is associated with recurrent calcium oxalate and/or phosphate stone disease [112]. Distal renal tubular acidosis (dRTA) has been reported in a significant proportion of affected patients, and hypercalciuria is present in nearly 50% of cases [112, 113]. Treatment with potassium citrate reduces stone recurrence in MSK.

Kidney stones have also been reported in 25–30% of patients with autosomal dominant polycystic kidney disease (ADPKD) [44, 114, 115], including uric acid (57%), calcium oxalate (47%), calcium phosphate (20%), and struvite (10%) stones [114]. Risk factors for stone formation in ADPKD include hypocitraturia, hyperuricosuria, hyperoxaluria, and hypercalciuria [114, 115]. Tolvaptan therapy significantly improves the urinary lithogenic risk profile in patients with ADPKD [116].

Increased frequency of urinary stones has also been described in patients with thin basement membrane disease [117].

Mechanism of Stone Formation

The pathogenesis of urinary stone disease in humans is complex and involves the interaction of genetic and environmental factors that vary according to the type of stone [118]. Kidney stones are thought to develop on structural lesions, driven by the urinary supersaturation of solutes. In 1937, Randall described renal papillary lesions which today are referred to as Randall's plaques and plugs; he hypothesized that stones only form and grow if attached to these lesions [119]. Currently, urinary calculi are thought to form by one of three major mechanisms [118]. First, kidney stones can develop on preexisting subepithelial interstitial plaques of calcium phosphate (Randall's plaques) that are present in the renal papillae. The second mechanism involves the deposition of crystals in renal tubules (Randall's plugs) that are primarily located in the inner medullary collecting ducts and in the ducts of Bellini (BD). Finally, stones can form in the fluid phase after crystallization of salts [118, 120].

The first pathway involves the formation of interstitial apatite or calcium phosphate Randall's plaques that probably originate in the basement membranes of the thin loops of Henle, from where they spread to the suburothelial space [121]. Randall's plaques are not associated with renal tissue damage [121]. Stones only form if plaques erode the papillary surface of the urothelium; once exposed, stone formation starts, driven by the urinary supersaturation of the stone forming salts [118]. Randall's plaques are very powerful triggers of stone formation, as indicated by the large number and size of calculi that grow attached to the small area of papillary surfaces (3.5–7.5%) covered with plaques [122, 123]. The plaque abundance on the papillary surface is associated with the number of urinary stones [124] and urinary calcium excretion, and is inversely associated with urinary volume and pH in idiopathic calcium stone formers, in obese patients that have undergone bariatric surgery, and in healthy individuals [123]. Since plaques form within the renal papilla, they are not thought to develop as a direct result of abnormal urinary supersaturating conditions, but idiopathic hypercalciuria, urinary pH, and urine concentration probably play a role [118, 123]. Hypothetically, increased water reabsorption increases calcium concentration along the loop of Henle, while urinary acidification raises pH in the papillary interstitium, favoring calcium phosphate deposition [118]. The thin limb basement membrane, which is comprised of negatively charged collagen and mucopolysaccharide molecules, attracts both calcium and phosphate through electrostatic forces [121]. In addition, the development of Randall's plaques depends on the stone type. It is present in nearly 100% of calcium and uric acid stones, 30% of cystine stones, and 20% of struvite stones [125]. Since idiopathic calcium stones are the most common type of urolithiasis, growth on Randall's plaque is the primary mechanism of stone formation in humans [118, 126]. Plaques are also observed in subjects without history of kidney stones [125], but tend to be larger in stone formers [121]. It is unclear at what age Randall's plaque begins to form; to date, no studies have analyzed Randall's plaque formation in the pediatric population [16].

Randall's plugs form when stone-forming salts precipitate and clog collecting ducts, protruding into the renal pelvis where they trigger stone formation and growth [118]. Plugging in the renal tubular lumen is driven by the urinary supersaturation of lithogenic factors and is generally associated with tubular epithelial injury and inflammation [120], contrary to Randall's plaques [121]. Different types of stones, including brushite, calcium oxalate, cystine, and calcium phosphate stones, have been found attached to Randall's plugs [120]. Plaques and plugs may coexist in patients with different types of stones, including patients with idiopathic calcium oxalate calculi [122, 127]. Linnes et al. [122] have shown that 99% of stone formers have Randall's plaques, but approximately 20% of patients also have tubular plugging, indicating that tubular plugging is more common than previously recognized and that the two mechanisms coexists in a significant proportion of patients [122].

The last mechanism of stone formation involves crystallization in the fluid phase of poorly soluble stone-forming molecules, such as cystine [118, 128]. Other highly insoluble salts, including DHA and xanthine, are likely to form stones by the same mechanism, although the exact pathophysiology has not yet been elucidated. Once anchored to a lesion, stone growth is driven by supersaturating conditions that are specific to the different stone types [63, 118].

The solubility or saturation point for the different stone-forming minerals or ions is the point of equilibrium at which crystals in solution neither grow nor dissolve [63]. A solution is undersaturated when crystals dissolve and supersaturated when crystals grow [55]. Urinary supersaturation values have been found to correlate with stone composition [129]. Urinary supersaturation is multifactorial, including concentration of calcium, oxalate, phosphate and sodium, urinary osmolality, urine pH, and complexation of stone-forming constituents with other molecules (e.g., magnesium, citrate, and urinary proteins) [63]. Acidic urine favors cystine (pH <7.5) and uric acid (pH <6.0) crystallization, while calcium phosphate stones form in more alkaline urine (pH >6) [42]. Calcium oxalate crystallization is not significantly influenced by pH in the physiologic range. Homogeneous nucleation (i.e., spontaneous formation of crystals in an oversaturated solution) is much less common than heterogeneous nucleation (i.e., formation of crystals on Randall's plaques or plugs or other types of crystals) [55, 63]. The human urine inhibits aggregation, nucleation, adhesion, and growth of calcium oxalate monohydrate crystals [130]. This explains why urinary calcium oxalate concentration is frequently above the solubility or saturation threshold, and crystals only form when the supersaturation reaches 7–11 times the solubility [55]. Interestingly, inhibition of calcium oxalate monohydrate crystal formation is inversely related to age; the urine of pediatric patients inhibits crystallization more effectively than adult urine [131]. This may, at least in part, explain why children form stones less frequently than adults [130]. Several proteins acting as crystallization inhibitors have been identified; of these, uropontin [132], nephrocalcin [133], and Tamm-Horsfall protein, also termed uromodulin, are most significant [63, 134, 135]. Citrate, pyrophosphate, and magnesium are the main nonprotein urinary crystallization inhibitors [63].

Genetics of Urinary Stone Disease

Family Studies

A positive family history has been reported in 25–65% of subjects with urinary stone disease in adults [136–139] and 33% of children [11].

Twin Studies

One twin study based on data from the Vietnam Era Twin Registry has estimated the heritability of urinary stone disease to be 56% [140]. In the same study, the concordance rate in monozygotic twins (32.4%) was significantly greater than the rate in dizygotic twins (17.3%) ($P<0.001$), consistent with a genetic influence.

Genealogy Studies

Familial clustering of kidney stones extends beyond the nuclear family in population-based studies from Iceland [141, 142]. In patients with radiopaque urinary calculi, the relative risk of stones ranged from 2.25 ($p<0.001$) for first degree relatives to 1.07 ($p<0.01$) in fifth degree relatives. The relative risk of urinary stones in parents and offspring of recurrent stone formers was >10 ($p<0.001$) [141]. Icelandic kidney stone formers were also found to be genetically more related to each other compared to the average Icelanders. These data provide strong evidence in support of a genetic component in the risk of developing kidney stones, and mitigate the effect of environmental factors.

Genome-Wide Association Studies

Linkage and candidate gene studies have been disappointing in identifying genes predisposing to develop urinary stones. Conversely, genome-wide association studies have been more successful [143, 144]. A study of 3,773 cases and 42,510 controls in Iceland and the Netherlands identified synonymous *CLDN14* sequence variants that associate with kidney stones, reduced bone mineral density, lower serum bicarbonate levels, higher urinary calcium excretion, and higher parathyroid hormone levels [143]. Approximately 62% of the general population is homozygous for these variants and has 1.64 times greater risk of developing kidney stones compared to noncarriers. CLDN14 protein is a member of the claudin family of membrane proteins that regulate paracellular passage of ions and small solutes at epithelial tight junctions [145]. Increased risk of urinary stones associated with *CLDN14* variants may result from the combined effects of changes in serum bicarbonate, urinary calcium, and parathyroid hormone levels. A second genome-wide association study conducted in 3,617 Icelandic and Dutch cases and 43,201 controls discovered a variant in the uromodulin gene conferring protection against kidney stones [144]. Uromodulin is a well-known urinary inhibitor of calcium stones [146]; variants in the uromodulin gene may reduce the ability of the protein to complex with urinary calcium, resulting in an increased risk of stone formation.

Rare Monogenic Causes of Urinary Stone Disease

Monogenic disorders account for approximately 10% of urinary stone disease in children and adolescents and 2% in the adult population [147]. These rare disorders are characterized by more severe stone disease, compared to common polygenic forms of stones. In addition they are frequently characterized by the development of CKD, secondary, at least in part, to crystal nephropathy. Their main features are summarized in Table 3; most of these disorders are covered in other specific chapters of this textbook.

Recurrent kidney stones and/or nephrocalcinosis, particularly in younger children, should therefore alert physician to the possibility of an underlying genetic cause. The lack of recognition of these disorders has frequently resulted in unacceptable delay in both diagnosis and treatment, sometimes with grave consequences [46, 148]. Clinical features that suggest rare monogenic causes of kidney stones are summarized in Table 4 [46].

Clinical Features

The acute presentation of urinary stone events in children is highly variable. Colicky abdominal, flank, or lower back pain is the most common presenting symptom in older children, and is reported in 50–80% of cases [11, 16]. Nonspecific abdominal pain and irritability are more common in younger children and infants [9]. Nausea and vomiting are often present. Gross hematuria is the presenting sign in 30 to 50% of cases; microhematuria is nearly always present during acute episodes [11, 16]. Other frequent features include urinary tract infections, lower urinary tract symptoms, or urinary retention if stones obstruct the bladder outlet or the urethra [9]. In some inherited conditions, acute kidney injury episodes may be underdiagnosed [149, 150], and only recognized retrospectively after patients have developed CKD [46].

Diagnostic Evaluation

Thorough medical history and physical examination, coupled with laboratory investigations and imaging are essential for the clinical evaluation of children with kidney stones. Medical history should focus on dietary information, episodes of

Table 4 When to suspect rare causes of kidney stones [46]. (Modified with permission from Springer Science and Business Media)

History	First stone as a child Family history of stones or nephrocalcinosis or unexplained kidney failure Brownish-red diaper stain[a] Growth retardation or rickets
Laboratory testing	Crystals of unusual type Cystine[b] 2,8-Dihydroxyadenine[a] Unidentified Mild-moderate proteinuria[c] Elevated serum creatinine and/or reduced GFR Hypomagnesemia and increased urinary calcium excretion[d] Increased urinary oxalate excretion[e] Positive urinary sodium nitropusside test[f] Significant hypouricemia[g] Persistent hypercalcemia or hypophosphatemia
Imaging	Nephrocalcinosis Radiolucent kidney stones Multiple stones, bilateral stones

GFR, glomerular filtration rate
[a] Suggestive of adenine phosphoribosyltransferase deficiency
[b] Diagnostic of cystinuria
[c] Low molecular weight proteinuria is suggestive of Dent disease
[d] Highly suggestive of familial hypomagnesemia with hypercalciuria and nephrocalcinosis
[e] May suggest primary hyperoxaluria
[f] Suggestive of cystinuria in children 2 years and older
[g] Suggestive of hereditary xanthinuria or idiopathic renal hypouricemia

dehydration, immobilization, use of nutritional supplements such as vitamin C, vitamin D, and minerals, and medications [9, 42]. A family history of urinary stones, hematuria, kidney failure, and/or metabolic disorders may be very informative. Clinical evaluation should look for features associated with disorders of mineral and vitamin D metabolism, including bone deformities, growth retardation, and signs of rickets or tetany [9, 42].

All childhood stone formers require a thorough laboratory evaluation following the first urinary stone episode to identify modifiable risk factors and to diagnose rare causes of stones, some of which may be associated with CKD (renal parenchymal lesions, proteinuria, evidence of tubular dysfunction, etc.) [42, 46]. Urine culture should be obtained if a urinary tract infection is suspected. Urine microscopy looking for urinary crystals should be performed at least once in all patients with kidney stones [46]. The characteristic round and brown DHA crystals (Fig. 2a) and hexagonal cystine crystals (Fig. 2c) are easily detected by urine microscopy and are diagnostic of 2,8-dihydroxyadeninuria and cystinuria, respectively. Calcium oxalate dihydrate crystals (Fig. 2d) are present in the urine of patients with high oxalate excretion, though they are also commonly seen in patient with idiopathic calcium oxalate stone disease and in non-stone forming subjects with concentrated urines. Patients with PH often have calcium oxalate monohydrate crystals in their urine, while in individuals with Dent disease, calcium oxalate or calcium phosphate crystals may be noted (Fig. 2e) [46]. Whenever stone fragments are available, their composition should be analyzed. The analysis of stone composition is diagnostic when calculi contain cystine, DHA, xanthine, and struvite [9, 42, 46]. Stone fragments should be collected by straining urine for several days following lithotripsy or a symptomatic stone event [105]. Although nonspecific, the finding of a calcium-based stone helps narrow the differential diagnosis and guides therapeutic approach. Since idiopathic uric acid stones are extremely rare in children, all pediatric uric acid stone

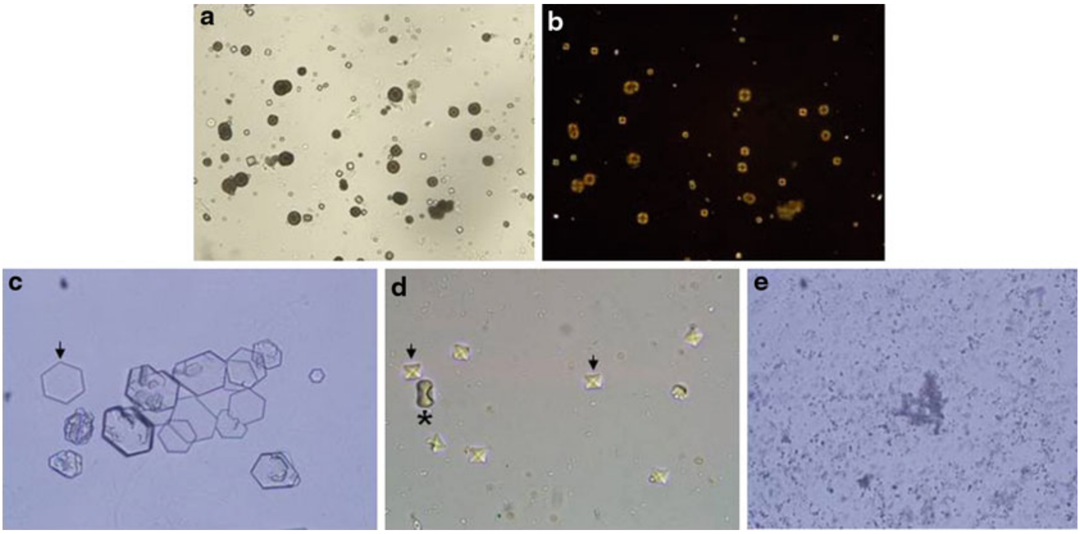

Fig. 2 Urinary crystals (Original magnification × 400). (**a**) The typical small and medium sized 2,8-dihydroxyadenine crystals. The medium sized crystals are brown with dark outline and central spicules. (**b**) The same field viewed with polarized light microscopy. The small and medium sized crystals appear yellow in color and produce a central Maltese cross pattern. (**c**) The typical six-sided cystine crystals are diagnostic of cystinuria. A good example can be seen on the left side of the Figure (arrow). (**d**) Urinary calcium oxalate crystals. The typical bipyramidal calcium oxalate dihydrate crystals (arrows) and a large dumbbell calcium oxalate monohydrate crystal (asterisk) are both seen. (**e**) Amorphous calcium phosphate crystals. Although their appearance is not as distinctive, amorphous calcium phosphate crystals should be suspected if the urine is alkaline (pH>6.0). (Reproduced with permission from Springer Science and Business Media)

formers should be screened for inborn errors of purine metabolism or renal tubular uric acid transport defects [46].

Comprehensive evaluation of urinary stone disease should also include serum electrolytes, bicarbonate, creatinine, blood urea nitrogen, and uric acid levels [105, 151]. Measuring serum concentrations of PTH, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D should also be considered. The 24 h urine excretion of calcium, oxalate, citrate, uric acid, sodium, and creatinine, as well as urinary volume and pH, should be measured, and, if possible, supersaturation profiles for calcium oxalate, calcium phosphate, and uric acid should be obtained after a first stone episode [9, 63, 152]. Normal values for urinary solute excretion in children are detailed in Table 2. In addition to measuring calcium and citrate excretion, assessing urinary calcium-to-citrate ratio can be very helpful for predicting stone formation and recurrence (Table 2) [153, 154]. Although 24 h samples are preferable for most urine parameters, random urine samples can be used in children who are not toilet trained. Since urinary solute excretion rates may vary significantly, repeat urine collections are frequently needed to confirm results.

Inherited metabolic disorders such as APRT deficiency, cystinuria, Dent disease, familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC), PH, and other rare disorders should be considered in the differential diagnosis of children with kidney stone disease and/or CKD, particularly when stones develop early, are multiple, and are bilateral [46]. Cystinuria should be ruled out with a qualitative (sodium nitroprusside test) or quantitative urinary cystine measurements [46]. LMW proteinuria should be ruled out in all boys with unexplained stones, nephrocalcinosis, and proteinuria, to exclude Dent disease [46]. Hypomagnesemia and hypercalciuria are strongly suggestive of FHHNC. In the absence of conditions causing fat malabsorption, hyperoxaluria should raise the suspicion of PH. Parathyroid hormone and vitamin D levels should be measured in patients with abnormal serum calcium and/or phosphate concentrations [46, 105].

In adults, non-contrast CT is the gold standard for imaging urinary stones [105]. Caution should be used when exposing children to ionizing radiations [151]. The American Urological Association and the European Association of Urology have developed separate guidelines for the imaging approach of children with urinary stone disease [151]. Both associations recommend using ultrasound as the first-line approach, and to use non-contrast CT only in children with a negative ultrasound but a high suspicion of urolithiasis [151]. Although ultrasound is less sensitive and less specific than CT [155, 156], it accurately identifies most clinically significant urinary stones in the pediatric population. In a cohort of 50 pediatric patients, the sensitivity and specificity of the ultrasound were 70% and 100%, respectively, compared to CT (gold standard), and the positive and negative predictive values were 96% and 62%, respectively [156].

Management of Acute Urinary Stone Events

Children with acute symptomatic stone events have pain, often have nausea and vomiting, and some may become dehydrated, all of which require prompt intervention [105]. Intravenous ketorolac is more effective than intravenous opioids for acute pain relief [157, 158]. In adults with renal colic, 56% of patients receiving ketorolac and 80% of patients receiving meperidine required repeat analgesia within 24 h in a prospective double blinded randomized study [159]. In children, several studies have documented that ketorolac is safe and effective for pain management in other conditions [160–162]. For example, one study compared 0.75, 1.0, and 1.5 mg/kg of intravenous ketorolac with 0.1 mg/kg of intravenous morphine immediately prior to dental surgery [163]. Ketoralac controlled pain as effectively as morphine and was associated with significantly less postoperative vomiting. Indirectly, these studies indicate that ketorolac is a valid first-line agent for pain management in children with a renal colic, while other analgesics, including acetaminophen and opioids, can be added if needed [105].

Stones larger than 5–10 mm in largest diameter frequently require surgical intervention. Early consultation with a pediatric urologist should be obtained in children with large stones. Different stone removal techniques are available. Very young patients can be offered ESWL, or minimally invasive techniques, including retrograde ureteroscopic or percutaneous lithotripsy (PCNL) [44]. ESWL is still recommended for upper tract stones up to 15 mm in diameter (largest diameter), although a significant number of stones require repeated treatments [164], and there is risk for parenchymal damage with this technique [165]. Open lithotomy is rarely required and has been replaced with noninvasive or minimally invasive techniques, thanks to the development of the small and versatile endoscopic instruments [164].

Antiemetic treatment is frequently necessary in patients with nausea and vomiting associated with acute urinary obstruction [105]. The most commonly used agents in pediatrics are serotonin antagonists, namely ondansetron, promethazine, and metoclopramide [166]. Ondansetron is typically used in the acute setting, while oral promethazine is usually prescribed for outpatient management [105]. Restoration of euvolemia is needed if patients are dehydrated [42, 105]. This usually requires intravenous administration of isotonic fluids, because oral hydration is often not tolerated. Overhydration in the intent to facilitate stone passage is contraindicated because it can increase pain and the need for more analgesics [105].

Outpatient management of children with symptomatic urolithiasis is possible if patients can drink. Medical expulsive therapy comprises the use of alpha or calcium channel blockers to facilitate ureteral stone passage, and is frequently attempted to prevent surgical procedures [151]. These treatments are based on the high densities of α_{1a}, α_{1d}, and calcium channel receptors in smooth muscle cells of the distal ureter and ureterovesical junction that allow alpha and calcium channel blockers to dilate the ureter [151]. To date, three pediatric studies have tested the efficacy of medical expulsive therapy [167–169]. The first study was underpowered and found no differences in stone passage rates between doxazosin and a placebo [167]. The second study showed higher stone passages in children treated with tamsulosin compared to placebo, but results should be interpreted with caution because half of patients in the tamsulosin group had been treated with ESWL [168]. The third study [169] evaluated retrospectively the effect of tamsulosin on the passage of stones less than 10 mm in largest diameter. After adjusting for stone size and location, the odds for spontaneous stone passage were 3.3 times higher in treated compared to untreated children. Overall, the level of evidence supporting the use of tamsulosin for ureteral stones in children is moderate [151], and the efficacy of doxazosin is unclear. In addition, the benefits of combined therapies with medical expulsive therapy and anti-inflammatory drugs need to be studied in children.

Spontaneous passage of ureteral stones in children has been found to be remarkably similar across all ages for stones measuring less than 5 mm, while passage rates decrease very significantly for larger stones [170]. Spontaneous stone passage in children is also similar or even superior to that observed in adults [105]. Therefore, conservative treatment, including medical expulsive therapy, should be attempted for pediatric ureteral stones less than 4–5 mm in size, when infection is not suspected, pain control is adequate, and patients do not have AKI (single renal system, bilateral obstruction). Patients are typically given a minimum of 2 weeks to allow for spontaneous stone passage before surgical/endoscopic intervention is considered [105]. Emergency obstruction relief or aggressive antibiotic therapy is indicated in patients with complete urinary obstruction or severe urinary tract infection [105].

Prevention of Urinary Stone Recurrence

Children with urolithiasis are at high risk of recurrence [6, 7]. Ideally, they should be seen every 1–2 years in a stone clinic by a dedicated medical team [105]. Patients with known metabolic risks and those who have relapsing stones need to be followed more frequently [44]. Patients who form new stones or have stones that increase in volume despite treatment need intensification of their therapy [44]. A full 24 h urine stone risk factor evaluation and assessment of kidney function should be performed at routine follow-up visits. Other tests must be tailored to individual needs. Ultrasound is the preferred imaging modality to assess changes in stone size [44]. The goal of medical treatment is to reduce urine supersaturation of stone-forming salts or minerals. A comprehensive treatment plan must include recommendations for (a) minimum fluid intake; (b) appropriate dietary changes; and (c) pharmacological treatment.

Fluid Intake

High fluid intake is the most important treatment for all patients with kidney stones. The minimum recommended intake in children with the common stone types is 1.5–2 L/m^2/day [42, 51]. During warm weather and physical exercise, fluid intake must be increased. Patients with hereditary metabolic conditions such as PH or cystinuria need larger urine output to adequately reduce urinary concentration and supersaturation of the respective stone forming salts (infants:>750 mL/24 h; 1–5 years: >1,000 mL/24 h; 5–10 years: >1,500 mL/24 h; older children and adolescents: >2,000 mL/24 h; older adolescents and young adults: >3,000 mL/24 h) [46]. Gastric tube placement may be necessary to achieve adequate hydration in very severe cases. The risk of stone recurrence is probably increased by the excessive consumption of sugary beverages [151] because fructose- and glucose-containing drinks increase urinary excretion of calcium and oxalate [171]; these should be avoided in stone formers [151]. Children with calcium stones may benefit from beverages rich in citrate such as lemonade and orange juice, although these drinks tend to contain considerable amounts of sugar [42].

Dietary Considerations

Quality studies of dietary interventions in pediatric stone disease have not been performed

[151]. Since sodium is known to increase urinary calcium excretion, limitation of sodium intake to 2–3 mEq/kg/day is recommended [42, 51]. Monitoring urinary sodium-to-potassium ratios may be useful to provide feedback when decreasing sodium intake and promoting potassium-rich foods [172]. Excessive animal protein consumption should be avoided [42]. Dietary purine intake parallels animal protein intake, and increases uric acid excretion in urines [151]. The recommended protein intake of children with urinary stone disease should be close to 100% of the recommended daily allowance (RDA) to ensure growth and development [42]. Children with acidic urine or hypocitraturia benefit from diets rich in fruits and vegetables [81]. The contribution of diet to urinary oxalate excretion may be significant [80]. Therefore, children with calcium oxalate stones and/or hyperoxaluria should avoid foods rich in oxalate (beets, chives, chocolate, green tea, nuts, okra, parsley, rhubarb, soy beans, spinach, star fruit, sweet potatoes, tofu, and wheat bran) and vitamin C supplements [42, 51, 105]. The optimal calcium intake in children and adolescents with urinary stone disease is not known. The risk of stone recurrence in prospective observational studies has been inversely associated with dietary calcium intake [173]. Low calcium diets do not prevent calcium stones and carry the risk of inducing hyperparathyroidism and compromising bone health; in stone formers, these diets offer no advantages over normal calcium diets with reduced animal protein and sodium content [24]. Children with urinary stones should be allowed normal dietary calcium in line with the RDA, but excessive calcium intake should be avoided [42].

Pharmacological Treatment

Pharmacological therapy is indicated in children with recurrent calcium-based stones or with treatable hereditary disorders causing urolithiasis (Table 5) [42, 51]. The goal of treatment is to reduce urinary concentration and supersaturation of stone-forming compounds. Urinary supersaturation can be lowered by (a) reducing the excretion of the stone-forming compounds; (b) complexation with inhibitors of crystal formation; and (c) manipulation of urinary pH.

The pharmacological treatment of patients with calcium stones and hypercalciuria includes thiazide diuretics that reduce renal calcium excretion [51]. This treatment should be limited to the most severe cases. Hydrochlorothiazide is the most commonly used drug, and the recommended dose is 0.5–2 mg/kg/day in children, given twice a day [42, 51]. The longer-acting thiazide compound chlorthalidone can be prescribed once per day, which may improve compliance. Monitoring of serum electrolytes should be performed, especially in young patients. Amiloride can be added to thiazides

Table 5 Treatment for metabolic stone disease [44]. (Modified with permission from Dawn Milliner, MD, Mayo Clinic, Rochester Minnesota and Springer Science and Business Media)

Metabolic abnormality	Initial Treatment	Second line Treatment
Hypercalciuria	Reduce dietary Na^+ Dietary calcium at RDA Thiazides[a]	Potassium citrate Thiazides Neutral phosphate
Hyperoxaluria	Reduce dietary oxalate Potassium citrate	Neutral phosphate Magnesium Pyridoxine[b]
Hypocitric aciduria	Potassium citrate	Bicarbonate
Hyperuricosuria	Alkalinization (K-citrate)	Allopurinol
Cystinuria	Alkalinization Reduce dietary Na^+	Thiola D-penicillamine Captopril

[a] If hypercalciuria is severe or there is osteopenia
[b] In pyridoxine responsive primary hyperoxaluria

in patients who develop hypokalemia and hypocitraturia, or if the hypocalciuric effect of thiazide treatment is suboptimal [105]. No pediatric studies have assessed the benefits of thiazides on stone recurrence. Randomized trials in adults have shown a 40–80% reduction in the stone recurrence rate of treated patients [151]. Caution should be used in combining thiazide treatment with potassium citrate supplementation; while these compounds compensate their effect on potassium, they both increase serum bicarbonate levels and may cause severe alkalosis.

Oral potassium citrate should be prescribed to children with calcium stones and hypocitraturia at doses of 2–4 mEq/kg/day (30–90 mEq/day in adults) [42]. Citrate binds to urinary calcium to form a soluble complex which decreases urinary calcium oxalate supersaturation; in addition, it directly inhibits crystal growth and aggregation [151, 174]. Citrate significantly increases the urinary alkali load. Therefore, care should be exercised preventing urinary pH to rise above 6.3–6.5 because the risk of calcium phosphate stone formation increases in alkaline urine [42, 151]. Clinical trials in adults have demonstrated a reduction in stone recurrence in patients treated with potassium citrate, while the evidence is less robust in children [151].

Children with urinary stones secondary to dRTA have chronic acidemia, hypercalciuria, hypocitraturia, and frequently form calcium phosphate stones [151]. The recommended treatment in this condition is potassium citrate in daily doses of 2–4 mEq/kg, which have been shown to normalize urinary calcium and citrate excretion, as well as serum bicarbonate levels [175]. The urine pH of these patients tends to be be high because of impaired proton excretion and alkali leak; urine pH should be monitored to prevent increasing urine pH above 6.3–6.5 [42, 151].

Children treated with ketogenic diets are at increased risk for kidney stones because they develop metabolic acidosis, hypercalciuria, hypocitraturia, and usually have low fluid intake; in contrast to children with dRTA, they have low urine pH [44, 151]. Stone composition includes uric acid, calcium phosphate, mixed calcium and uric acid, and ammonium urate [44]. Potassium citrate reduces the incidence of urinary stones in these patients; prophylactic potassium citrate treatment has been proposed during ketogenic diet [176].

Treatment of children with pure uric acid stones includes alkali therapy aiming at urinary pH not exceeding 6.5, to avoid the risk of calcium phosphate stone formation. These patients tend to have low urine pH and are best treated with potassium citrate with average doses of 1–2 mEq/kg/day divided in two daily doses [151].

Oral administration of neutral phosphate and magnesium preparations, which bind urinary calcium and oxalate, respectively, may reduce the risk of forming stones in selected patients.

Treatment of hereditary monogenic causes of kidney stones (APRT deficiency, cystinuria, Dent disease, PH) is described in other chapters of this textbook.

Abstract

Urinary tract infection (UTI) remains among the most common bacterial infections in childhood. An association between UTIs and abnormalities of the renal tract, particularly vesicoureteral reflux, has long been recognized. Concern that episodes of pyelonephritis might result in significant damage to the kidneys culminating in chronic kidney disease (CKD) or even end-stage kidney disease has been tempered in recent times; moreover, any existing CKD is now recognized as predominantly congenital in origin. Recurrent infections, particularly febrile UTIs, do still however have accompanying morbidity. This chapter will address all aspects of childhood and adolescent UTI with particular emphasis on our current understanding of the pathophysiology, diagnosis, and management.

Urinary tract infection · Pyelonephritis · *Escherichia coli* · *Diagnosis* · *Management* · *Antibiotics* · *Ultrasound* · Pediatrics · Cystitis · Immunity

Introduction and Background

In pediatrics, urinary tract infection (UTI) is the second most common bacterial infection affecting 7–8% of girls and up to 2% of boys in the first decade of life [1]. UTI is more predominant in males during the first year of life and girls thereafter and in most cases responds readily to treatment (Fig. 1). Among children who develop a UTI, up to 30% will develop a second infection. Over half of recurrent UTIs are caused by the same bacterial strain identified during the initial infection [2].

UTI is termed cystitis when the infection is confined to the bladder and urethra, with localized symptoms including dysuria, frequency, malodorous urine, and diurnal and secondary nocturnal enuresis. Acute pyelonephritis is a more significant infection that involves the renal parenchyma. Most affected children, particularly infants, appear systemically unwell with high fever, which may be the only feature. Febrile infections have caused the most concern as they place the kidney at risk of scarring with potential long-term sequelae. Asymptomatic bacteriuria is thought to be a variant of UTI by some and completely distinct from UTI by others, whereby a significant growth of organisms occurs on culture of the urine in the absence of any symptoms. It has been found on screening in approximately 1% of school-aged girls, but it does not require treatment or investigation as the outcome is excellent and uninfluenced by any intervention.

An association of UTI with kidney and urinary tract abnormalities has long been recognized, particularly when the infections are recurrent or febrile. When UTIs have been investigated with invasive imaging modalities, small hypo-dysplastic and scarred kidneys often

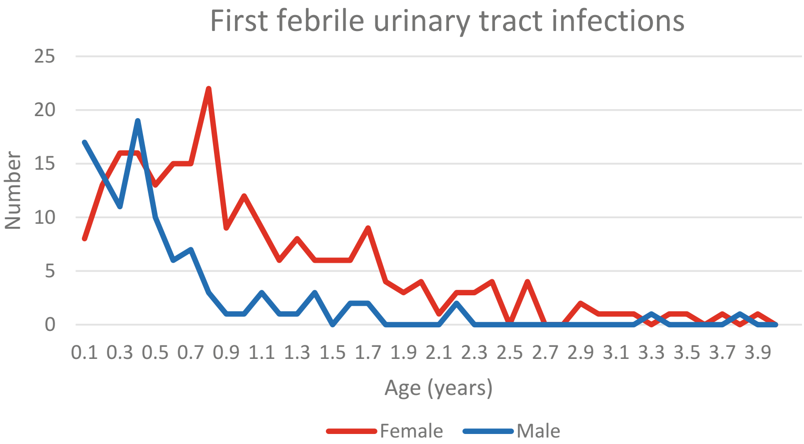

Fig. 1 Age at presentation of a first febrile UTI in 329 children (F 224, M 105) aged less than 4 years. Data abstracted from two prospective RCTs (IRIS 1&2)

with vesicoureteral reflux (VUR) were frequently found. The concept of reflux nephropathy was conceived to represent kidney damage predominantly attributed to ascending infections secondary to VUR resulting in renal scarring [3]. Children with reflux were often placed on long-term antibiotic prophylaxis or underwent ureteric reimplantation. Two early studies randomized children with VUR, detected following a UTI, to antibiotic prophylaxis or surgical correction alone or associated with adjuvant prophylaxis. Both studies demonstrated comparable satisfactory outcomes in the absence of a control (no treatment) or placebo group [4, 5]. The widespread introduction of prenatal ultrasound commencing in the 1980s demonstrated that much of the renal damage, often familial and detected in association with high-grade reflux, was the consequence of congenital abnormalities of the kidney and urinary tract (CAKUT) [6]. This led to a reevaluation of the role of acquired pyelonephritic scarring as a contributor to chronic kidney damage.

Clinical Presentation

There is considerable variability in the presentation of pediatric UTIs. UTI symptoms are influenced by the age at presentation, level of infection, nature and virulence of the organism, and the child's innate immune response. In newborns and infants, fever may be the only presenting symptom, while other nonspecific symptoms may include prolonged neonatal jaundice, irritability and listlessness, vomiting, slow feeding, and poor weight gain. There is a predisposition for UTI in infants to result in septicemia, including the possibility of meningitis [7, 8].

Symptoms localized to the urinary tract including frequency and dysuria are not usually apparent until 2–3 years of age. Flank pain secondary to pyelonephritis, even if present, is not generally reported by the child until 4–5 years of age. When the temperature is 38.5 °C or higher, the likelihood of renal parenchymal infection is increased, although cystitis per se can be present with fever.

In older children, voiding problems including hyperactive and dysfunctional bladder emptying may be associated with recurrent cystitis and less commonly recurrent febrile UTIs (see Chap. 59, Bladder Disorders). Thus, in these children a precise history of voiding patterns including continence, diurnal and nocturnal enuresis, frequency, urgency, and bowel habits is important [9, 10]. Although all children are susceptible to UTI, UTI risk is heightened in select populations (Table 1).

UTI Etiology

The common causative uropathogens originate in the fecal flora. *Escherichia coli* (*E. coli*) is the most frequent bacterial pathogen responsible for cystitis and pyelonephritis accounting for 85–90% of cases [2, 11]. However, other Gram-negative bacteria

Table 1 Pediatric populations with increased UTI susceptibility

Population	Rationale
Neonates and infants	• UTI risk has been attributed to an incompletely developed immune system.
Circumcision status	• In the first year of life, non-circumcised boys have increased UTI risk. • Uropathogens colonize areas under the prepuce, increasing the risk for urethral invasion and subsequent UTI .
Constipation and Gastrointestinal dysbiosis	• A stool-filled colon may compromise bladder emptying and increase UTI risk. • Antibiotic and immune-mediated disruptions of the gastrointestinal microbiota trigger inflammation and pathogen colonization that can increase UTI risk.
Immune response	• Alterations in the innate immune defenses may predispose children to UTI. • Polymorphisms in genes encoding pattern recognition receptors, cytokines, transcription factors, and host defense proteins are associated with childhood UTI predisposition .
Functional urinary tract disorders	• The inability to empty the bladder, with dysfunctional elimination syndrome or neurogenic bladder, results in urinary retention, urinary stasis, and inadequate pathogen clearance. • Elevated bladder pressures, secondary to poor drainage, may cause secondary VUR and potentiate kidney injury with pyelonephritis.
Anatomic urinary tract disorders	• Congenital kidney or urinary tract anomalies can result in urinary obstruction or stasis, increasing UTI susceptibility by reducing pathogen clearance. • Infections associated with urinary tract anomalies often appear in children younger than 5 years of age.
Systemic disorders	• Diabetes mellitus, sickle cell disease, and other immunocompromised states (HIV/AIDS, solid organ transplants) increase UTI risk.
Spinal dysraphism	• Myelomeningocele often leads to neurogenic bladder, which increases UTI risk. • People with spinal cord disorders may require intermittent catheterization which can lead to asymptomatic bacteriuria or UTI.
Sexual activity	• Sexual activity is a UTI risk factor in young women. • The proposed mechanism is the transfer of bacteria from the bowl or vagina to the urethral meatus during sexual intercourse.

colonizing the gastrointestinal tract cause UTI, including *Klebsiella, Pseudomonas, Proteus, Enterobacter, and Citrobacter* species. Certain Gram-positive organisms can also cause UTIs. *Enterococcus* species are the causative pathogens in both community- and hospital-acquired UTI. *Streptococcus agalactiae* is relatively common in newborn infants. *Staphylococcus saprophyticus* is seen in sexually active female adolescents, accounting for >15% of UTIs. In children with CAKUT or a compromised immune system, *Staphylococcus* and S*treptococcus* species also may be responsible [10, 11, 12]. Viruses and fungi are also relatively uncommon causes of UTI in children [13].

Cystitis Pathogenesis

Urinary tract infection occurs via the retrograde ascent of bacteria. Uropathogenic *E. coli* (UPEC) are excreted with the feces, colonize and spread across the perineum, ascend the urethra, and invade the bladder. Over the last two decades, a mosaic of UPEC virulence factors including adhesins, toxins, capsule composition, siderophores, and flagella have been identified to promote UTI (Fig. 2) [14]. To initiate cystitis, UPEC produce filamentous adhesive organelles called type 1 pili that bind uroplakins on superficial bladder urothelial cells. Adherence to the urothelium prevents UPEC from being cleared by the shear flow of urine during bladder emptying. Of note, atypical UTI pathogens that do not produce these adhesins are more likely to cause UTI when urine drainage is impaired (e.g., CAKUT, acute obstruction, nephrolithiasis, etc.) [15].

Attachment is the key event initiating UPEC UTI. Once bound, urothelial cells internalize UPEC. This internalization allows UPEC to enter a nutrient-rich cytosolic niche where they proliferate to form large, dense intracellular aggregates called intracellular bacterial

Fig. 2 Uropathogenic *E. coli*-associated fitness and virulence factors Shown is a representation of different factors that promote the virulence of uropathogenic *E. coli* (UPEC) strains. (**Left**) These factors include iron acquisition systems like siderophores. (**Right**) UPEC strains produce and secrete toxins that disrupt host membrane trafficking, cytoskeletal rearrangements, immune and inflammatory responses, and survival pathways. Depicted are the toxins that disrupt host cell integrity including cytotoxic necrotizing factor 1 (CNF1), secreted autotransporter toxin (Sat), and alpha-hemolysin (HlyA) as well as immune-activating proteins such as lipopolysaccharide (LPS). (**Bottom**) UPEC use multiple adhesins to bind proteins expressed on host bladder and kidney uroepithelial cells to cause infection [14]

communities (IBCs). IBCs develop from a single bacterium and ultimately contain up to 10^5 organisms that are encased in a highly organized polysaccharide matrix resembling an intracellular biofilm. IBCs are protected from antibiotics, neutrophil influx, and other host immune defenses. As the IBC matures, it engulfs the host nucleus [15, 16, 17, 18].

Within the IBC, UPEC replicate, differentiate, and develop filaments that extrude from the infected cell. Ultimately, UPEC dissociate from the urothelial cell and flux into the bladder lumen. Filamentous UPEC attach to neighboring bladder cells, reinvade the urothelium, and create additional IBCs. To limit infection, superficial urothelial cells containing IBCs are exfoliated to aid in the clearance of tissue-associated UPEC. This spurs the proliferation of intermediate and basal cells to regenerate and restore the urothelium [18, 19]. Exfoliated IBCs have been detected in the urine of women with UTI [20]. After exfoliation, UPEC may invade the underlying basal urothelium and establish a quiescent intracellular reservoir (QIR). Although the latent QIR population is small (containing only up to 12 bacteria), it is considered a major source of recurrent UTI [21, 22].

Pyelonephritis Pathogenesis

Although the pathogenesis of cystitis has been extensively investigated, the interactions between UPEC and kidney epithelial cells are less defined. Recent studies demonstrate that UPEC must be motile to establish pyelonephritis. UPEC strains lacking flagellin and the motor proteins MotA and MotB cannot ascend into the kidney [23, 24]. Upon reaching the kidney, UPEC concentrate in the medullary collecting tubules and preferentially attach to mitochondrial-rich α-intercalated cells. UPEC target intercalated cells because they are endocytically active and serve as an avenue of entry into the renal interstitium [25, 26, 27].

To bind medullary epithelial cells, UPEC must express type 1 fimbriae, which bind to the glycosphingolipids and mannosylated glycoproteins expressed on the surface of renal epithelial cells [28]. Translocation across kidney tubular cells occurs by two different mechanisms – paracellular and transcellular migration. UPEC possessing the virulence factor *hlyA* and *sat* (encoding α-hemolysin and a secreted vacuolating cytotoxin, respectively) activate caspase 3. Caspase 3 activation induces renal epithelial cell apoptosis, disrupting the tubular epithelial tight junction barrier and thereby promoting paracellular UPEC migration. UPEC strains lacking *hlyA* and *sat* cannot alter the tight junction complexes. Instead, these UPEC strains remodel the actin cytoskeleton and translocate across the cell in a Toll-like receptor 4 (TLR4)-facilitated fashion [26, 29].

Host Immune Response

The host utilizes several innate defenses to prevent UTI. Proposed antibacterial mechanisms limiting uropathogen attachment and invasion include epithelial barrier formation, the unidirectional flow of urine, routine bladder emptying, alterations in the urinary ionic composition, urinary and gastrointestinal microbiome homeostasis, and the production of antimicrobial peptides (AMPs) that inhibit bacterial attachment or directly lyse invading pathogens [30].

In the urinary tract, AMPs are produced by the uroepithelium of the bladder, ureter, and kidney tubules. In the kidney, intercalated cells are the primary AMP producers. The AMPs kill pathogens, disrupting the integrity of bacterial cell membranes, and have other antimicrobial assets. For example, AMPs block pathogen replication, bind specific targets to disrupt energetic processes, sequester vital nutrients like iron or other metals, promote bacterial opsonization, and interfere with bacterial toxins. In addition, AMPs interact with host cells to modulate innate and adaptive immune responses or promote epithelial regeneration. AMPs identified in the kidney and urinary tract include calprotectin, defensins, cathelicidin, hepcidin, lactoferrin and lipocalin 2, ribonucleases, and uromodulin. Cross-sectional studies in girls with recurrent UTIs suggest that deficient AMP production may be a UTI risk factor [15, 31, 32].

If bacteria overcome these innate immune defenses and attach to the bladder urothelium or kidney epithelium, they trigger a host inflammatory response that results in the production of distinct inflammatory mediators including inflammatory cytokines and chemokines, complement activation, and AMPs [31, 32, 33]. The bladder urothelium and kidney's intercalated cells play key roles in orchestrating these effectors. This response is followed by the activation of innate immune cells and proteins that migrate to the infectious focus and facilitate eradication of the invading bacteria. While these innate immune responses effectively eradicate invading pathogens, the resulting inflammation may lead to tissue injury [15, 32].

Mechanisms of Kidney Scarring

Although it is well recognized that acute pyelonephritis (APN) in children may lead to kidney scarring, the pathogenesis or mechanisms by which kidney inflammation leads to tubulointerstitial fibrosis are not well defined. Evidence indicates that kidney scarring is a consequence of excessive inflammation and bacterial infiltration [34, 35]. This inflammatory reaction, which is triggered to eradicate invading bacteria, leads to tubular cell injury, macrophage and neutrophil infiltration, and activation of pericytes and myofibroblasts. Within the kidney, the activated myofibroblasts are widely accepted to be the primary cellular driver of fibrosis. Myofibroblast activation is driven by transforming growth factor beta, which is secreted by injured tubules and activated macrophages [36]. In addition to myofibroblast activation, experimental evidence shows that dysregulated macrophage-dependent inflammatory responses promote kidney damage and fibrosis [37].

Unlike other kidney injury paradigms such as unilateral ureteral obstruction or ischemia-reperfusion injury, APN leads to an ascending pattern of fibrosis [38, 39]. With APN, fibrosis initiates deep to the urothelium in the kidney's pelvis and is identified by expansive submucosal connective tissue deposition. This collagenous deposition spreads through the interstitium to the outer medulla and cortex. Ultimately, this gives rise to the wedge-shaped patterns of renal parenchymal injury identified in children following APN [40, 41].

Diagnosis of Urinary Tract Infection

UTIs are diagnosed upon the culture of a single organism in sufficient numbers from an appropriately collected urine specimen. Laboratories employ a standardized technique sampling 0.001–0.002 ml (1–2 μL) of urine in a sterile loop plating it out on a culture medium and incubating in room air at 35° C, with the plates checked for the type and number of colonies. Dipslide cultures provide an alternative, particularly for after-hours collection of specimens, thus enabling earlier reporting of culture results. Urinalysis is a useful adjunct in the diagnosis, particularly as culture results may take 24–48 hours, but never obviates the need for urine culture. Various methods of urine collection for culture are employed including suprapubic bladder aspirate (SPA), catheter specimens (CSU), midstream-voided specimens (MSU), and bag specimens each method having progressive increases in the likelihood of bacterial contamination. The threshold level for a significant growth of organisms to define a positive culture based on an MSU was first set by Kass 60 years ago at $\geq 10^5$ organisms/ml, based on pyelonephritis studies in pregnant women [42]. Kass acknowledged at the time that such a threshold would result in missed UTIs, which is also true in the pediatric population. A recent study of infants <1 year of age with a symptomatic UTI diagnosed by suprapubic aspirate demonstrated that 19% had colony counts $<10^5$ of whom 87% had counts $<5 \times 10^4$ [43]. An editorial comment on this subject noted that diagnosing a UTI based on a strict threshold level was inappropriate [44]. Most published guidelines on diagnosis of UTI in children avoid a detailed discussion of what constitutes an infection. Recently the Diagnosis of Urinary Tract infection in Young children (DUTY) study attempted to validate a clinical algorithm for the diagnosis of UTI in those who presented with an acute illness in the primary care setting. Pads were used for sample collection in infants, and clean-catch specimens were used in older children. Unfortunately, disagreements persisted on UTI diagnosis between government and research facilities, although most agreed that clean catch was the preferred collection method [45].

Contamination during collection proved a particular problem creating difficulty with interpretation of urine cultures. Contamination can occur during collection by organisms from the urethra or periurethral area, genitalia, and surrounding skin. Suprapubic aspiration of urine and samples obtained by percutaneous nephrostomy is considered the "gold" standard for diagnosis of UTI, due to the reduced risk of contamination, with any organism cultured generally considered to be significant. Ideally, suprapubic aspiration is performed with ultrasound guidance; however, the invasive nature (leading to patient and family objections) and skill required for the procedure often preclude its use. Urethral catheterization is the next most effective method of obtaining a culture specimen with a growth of 10^3–10^4 colonies per ml typically considered significant. As with suprapubic aspiration, parents may consider this stressful for the child, with the additional concern that infective organisms may be introduced by the procedure. A midstream-voided specimen represents the most practical method, particularly after children are toilet trained and able to void on request. Presently, most agree that a positive culture consists of one with growth of a single organism $\geq 10^5$ colonies per ml or $\geq$ 50,000 colonies per ml of a single organism accompanied by pyuria [46]. Many groups (and some national guidelines) believe that midstream samples should have both a significant colony count on urine culture and urinary leukocytes for the diagnosis of UTI [47]. The presence of pyuria can assist in the differentiation between contamination, colonization, and clinically significant infection. When sterile leukocyturia is present, urine antibacterial activity should be sought out; if no antibiotics were administered prior to urine collection for culture, consideration should be given to the presence of atypical bacteria such as *Ureaplasma* and/or *Gardnerella* species that require non-standard culture media. In addition, other inflammatory conditions such as hypercalciuria or Kawasaki disease should be considered along with tuberculosis in endemic areas. The culture of multiple organisms increases the likelihood of contamination such that a culture should be repeated [9].

While not always successful, clean-catch urine specimens may be possible in infants and young children as they void frequently. One study reported a success rate of 86% in newborns, using a bladder and lumbar stimulation technique to obtain a midstream urine specimen with a median time of sample collection of 43 seconds [48]. Bag collections are practiced in primary care settings [49] and are of use as a screening procedure to perform urinalysis. If leukocyturia is present, a definitive urine collection and culture such as an MSU or CSU should be performed. The use of bag collections as the sole method to perform a culture is discouraged and contraindicated in all published guidelines [50].

A presumptive diagnosis of UTI and subsequent treatment is often guided by the findings on preliminary urinalysis and clinical presentation, prior to the culture results. If a UTI is strongly suspected, such as when leukocyturia and fever are present, it is appropriate to initiate antibiotic treatment before culture results, taking into consideration local drug sensitivities and resistance patterns. Urine samples can be examined by microscopy and/or urine dipsticks. Urine dipsticks are quick, easy to perform, and cost-effective. As noted above, leukocyte esterase positivity in the urine is a strong indicator of pyuria. As regards the nitrite test, most uropathogens produce nitrite from nitrate, although it may take up to 4 h to generate sufficient nitrite. This explains why infants and children with urinary frequency often have a false-negative test. Gram-positive infections, such as those from *Enterococcus*, will also not present with nitrites. A positive nitrite test cannot be relied upon in isolation, as it can be positive with asymptomatic bacteriuria and hence requires significant pyuria for conformation [47]. Recently the revised Italian guidelines note that the presence of white blood cells in the urine, with or without a positive nitrite test, allows for the presumptive diagnosis of UTI [47]. Hence, urine dipsticks offer a fast, easy, and cost-effective means of directing the initial management and treatment. Future studies are needed to determine the most suitable method of urine sampling, the correct thresholds for the culture counts depending on the methods of urine collection in children, and the significance of positive urine cultures in the absence of leukocyturia.

Differentiating Upper from Lower Urinary Tract Infections

The differentiation between upper and lower tract UTIs is not always apparent during the acute presentation. No markers exist that reliably predict the presence of acute pyelonephritis. C-reactive protein and white cell counts are often elevated but are insufficiently sensitive and specific for the diagnosis of renal parenchymal infection. Procalcitonin, a calcitonin precursor, released by the thyroid gland in response to bacterial infections, is currently the most reliable blood test of pyelonephritis and of subsequent renal scarring [51]. A number of urinary markers have been shown to increase during pyelonephritis as opposed to cystitis. These include INF gamma, IL15, and chemokine ligands CXCL1, CXCL9, and CXCL12; however none has proved better than procalcitonin [52]. The “gold standard” for the diagnosis of acute pyelonephritis remains the technetium-99 m-labeled dimercaptosuccinic acid (DMSA) scan (see Chap. 6 on Diagnostic Imaging). In the past, this imaging test had been proposed as an initial investigation within the first week of infection. Presently its use has declined in this context, given the significant radiation dose and lack of availability in many non-tertiary centers. Potential blood and urine markers are continuing to be evaluated by investigators. For practical purposes, fever in association with a UTI is considered pyelonephritis in the clinical setting [53, 54].

Treatment of an Acute UTI

With their advent, antibiotics have become the cornerstone for UTI treatment resulting in dramatically improved outcomes. In the early twentieth century, infants and young children hospitalized with acute pyelonephritis frequently died as a consequence of their disease [55]. Despite the recognized effectiveness of antibiotics in treating UTIs, until the mid-1990s little research had been conducted on the appropriate agent(s), manner of administration, and duration of treatment. Uncomplicated afebrile UTIs were and generally continue to be treated with oral antibiotics with a high renal excretion and a more narrow spectrum. A recent systematic review of antibiotic treatment for uncomplicated lower UTI in children concluded that short-course oral therapy (3–7 days) was as effective as long-course (7–10 days) treatment; however, single-dose therapy is not recommended until further studies are undertaken to determine its effectiveness [56].

In contrast, treatment for febrile UTIs, particularly in infants and younger children, typically included hospital admission and broad-spectrum intravenous antibiotics. Between 1995 and 2004, five clinical trials demonstrated that short courses of intravenous antibiotics (up to 4 days) followed by oral therapy were as effective as longer courses of intravenous treatment (7–14 days) [57, 58, 59, 60, 61]. Four studies involving a total of 1344 infants and children as young as 1 month of age with a first febrile UTI went further, demonstrating that oral administration of antibiotics was as effective as initial intravenous followed by oral antibiotics. The studies showed no difference in time to resolution of fever or in occurrence of subsequent renal damage [62, 63, 64, 65].

Most current guidelines for treatment of a febrile UTI recommend oral antibiotic administration on an outpatient basis, with hospital admission and parenteral administration restricted to those children who appear to be severely ill, who are vomiting and/or with whom poor adherence is a risk [66, 67]. The choice of antibiotic should be guided by local antibiotic resistance patterns and aimed toward the most common causative pathogenic bacteria. Amoxicillin/clavulanate and cephalosporins are typically used antibiotics both for oral and iv administration, where local sensitivities permit. In many areas of the world, UPEC producing extended spectrum beta-lactamase (ESBL) is of concern [68]. Ampicillin-sulbactam could be used as first-line treatment, depending on local availability [47]. Antibiotics commonly used and dosages suggested by different guidelines are listed in Table 2. Provided an organism is sensitive, no antibiotic has been shown as superior to another. Many support the use of iv cephalosporins (cefotaxime or ceftriaxone) in children with severe infections, as these antibiotics have a superior efficacy and onset of action, making the possibility of resistance a less likely. In the case of a breakthrough infection in children on antibiotic prophylaxis, a change of antibiotic becomes necessary, because of an almost certain resistance to the prophylactic agent [69].

Infants in the first month of life who present with unstable temperature, lethargy, poor feeding, and/or prolonged jaundice may be septic and warrant intravenous antibiotics after blood and urine cultures are taken. Sepsis in the first 72 hours is most commonly from *group B streptococcus*, although UPEC infections can occur in this period and become more common thereafter. Neonatal sepsis is recognized as a serious illness, particularly when it occurs in low birth weight preterm infants. Bacterial infections in infants tend to be more severe due to an immature immune system and, in the case of preterm infants, reduced placental transfer of protective maternal antibodies. Thus, intravenous penicillin class antibiotics combined with aminoglycosides are commonly used on an empiric basis. Care should be taken to monitor aminoglycoside levels because of their potential nephrotoxicity, particularly in infants with impaired renal function secondary to renal dysplasia.

Table 2 Antibiotics and dosages recommended by international guidelines for the treatment of UTI

	AAP	CARI	ISPN	Comment
Oral antibiotics mg/kg/day				Oral antibiotics preferred in well-appearing children as equally efficacious to iv therapy
Amoxicillin-clavulanic acid	40 in 3 doses	22.5 + 3.2 in 2 doses	50–90 in 3 doses	
Cephalexin	50–100 in 4 doses	50 in 4 doses	–	
Cefixime	8 (max: 400/day) in 1 or 2 doses	–	8 twice the first day once daily thereafter	
Ciprofloxacin	Not recommended as empiric treatment	25 in 2 doses*	20–40 in 2 doses*	*use where resistance to other abs or *Pseudomonas* infection
Trimethoprim-sulfamethoxazole	6–12 (trimethoprim) in 2 doses	8 (trimethoprim) in 2 doses	8–12 (trimethoprim) in 2 doses	
Intravenous antibiotics mg/kg/day				Recommended in children who appear septic or cannot tolerate oral abs. Change to oral when clinical improvement
Ampicillin-sulbactam	100–200 (ampicillin) In 4 doses		100 (ampicillin) in 3–4 doses	
Amoxicillin-clavulanic acid			100 (amoxicillin) in 3–4 doses	
Cefotaxime	150–180 in 3 doses	75 in 3 doses	150–200 in 3–4 doses	
Ceftriaxone	75 single dose	25 single dose	75–100 single dose	
Amikacin	15–22.5 single dose		15 single dose	Need to adjust dosage for renal function and serum levels
Gentamicin	5–7.5 single dose	<10 years: 7.5 ≥ 10 years: 6 single dose	6–7.5 single dose	

Local drug recommendations should always be consulted regarding contraindications, side effects, maximum prescribed dosage, and duration of therapy. The NICE (National Institute for Health and Care Excellence) guidelines do not provide specific details on drug dosages. *AAP* American Academy of Pediatrics, *CARI* Caring for Australian and New Zealanders with Kidney Impairment, *ISPN* Italian Society of Pediatric Nephrology

Imaging

No clear consensus exists regarding imaging after a UTI, although a better understanding of infections and their sequelae has led to fewer procedures. Most existing protocols focus on imaging in infants and younger children with febrile UTIs; however, few recommendations exist regarding afebrile UTIs and/or those occurring in older children. Some of the imaging modalities that can be considered in these patients are listed below (also see Chap. 6 on Diagnostic Imaging).

Ultrasonography

Ultrasonography can detect a variety of anatomical abnormalities and is noninvasive but is dependent upon the expertise of the sonographer. The widespread implementation of antenatal ultrasound has been of value in detecting the majority of significant congenital abnormalities of the kidney and urinary tract (CAKUT), including kidney hypodysplasia, obstruction at the pelviureteric and vesicoureteric junctions, and posterior urethral valves [70]. Kidney and bladder ultrasound (KBUS), performed after a febrile UTI, did not reliably reveal the presence of VUR or subsequent scarring in three prospective trials, involving 864 children. Minor congenital abnormalities that had little influence on subsequent outcomes were found in 12 to 14% of cases [71, 72, 73].

The value of performing a routine KBUS following an uncomplicated febrile UTI has been increasingly questioned (Table 3). The American Academy of Pediatrics (AAP) [46] and the Italian Society of Pediatric Nephrology (ISPN) [66] recommend US in all children under 2 years of age following an initial febrile UTI; however, the National Institute for Health and Care Excellence (NICE) guidelines restrict US to <6 months of age [67], and the Australian guidelines (CARI) do not recommend US except in the absence of an antenatal study or in the presence of other risk factors [74].

Given the paucity of KBUS findings following an uncomplicated UTI in childhood in areas where second and/or third trimester antenatal US shows normal anatomy, most believe a KBUS is unnecessary. However, in areas where access to antenatal care and health services is limited, most recommend that a KBUS be performed. If the infection is atypical (caused by a non-UPEC organism, lacks an appropriate antibiotic response), renal damage is suspected, a weak urine stream occurs, or recurrent infections are present, then a KBUS should be performed [75, 76, 77]. In older children, a KBUS is suggested after recurrent UTIs, once a detailed voiding history has been assessed. In these patients, the KBUS should also be used to evaluate bladder filling and emptying, the residual urine post micturition, and bladder wall thickness both full and empty (the bladder wall full is usually less than 3 mm and empty less than 5 mm) (see Bladder Disorders, Chap. 59). Significant abnormalities on bladder ultrasound warrant consideration of urodynamic studies.

Voiding Cystourethrography

Voiding cystourethrography (VCUG) involves serial imaging of the low urinary tract following the instillation via urethral catheterization of a radiopaque contrast media. VCUG tests can detect the presence of VUR, urethral obstruction due to posterior urethral valves in boys, ureteroceles, and/or bladder changes such as those consistent with a neurogenic bladder. This study has led to controversy given the distress this invasive procedure can cause parents and children. Advocates of VCUG, predominantly surgeons [78], cite a strong association between the severity of reflux and presence of renal damage [75], now recognized as predominantly congenital rather than acquired [79, 80].

Most guidelines support a selective approach to this investigation, citing the lack of evidence that medical or surgical interventions are typically useful, except possibly in children with high-grade reflux [81]. Most recommend a VCUG in children following a febrile UTI in the first 2–3 years of life if the KBUS is abnormal or the UTI atypical (Table 3). The Italian guidelines also identify specific US abnormalities that represent an indication to perform a VCUG, including uni- or bilateral renal hypoplasia, abnormal renal parenchymal echogenicity, ureteral dilatation, uroepithelial thickening of the renal pelvis, and pelvi-calyceal dilatation, particularly if associated with bladder uroepithelial thickening, and other bladder abnormalities [82]. Regarding atypical UTI, a recent article has confirmed that the presence of a pathogen other than UPEC significantly predicts reflux [83]. Thus, a reasonable approach would include a VCUG following a first febrile UTI in children less than 2 years of age with major abnormalities of the urinary tract or kidneys on KBUS and a poor urine stream or when a non-UPEC infection is diagnosed. Recurrent febrile UTI also represents an indication for VCUG. In older children with febrile UTIs or recurrent cystitis, most believe that a VCUG is rarely indicated, since an ultrasound and detailed history of voiding patterns are usually sufficient to establish the diagnosis and initiate treatment.

Table 3 Published guidelines on the investigation and management of a first febrile UTI

Guideline	Ultrasound	VCUG	DMSA	Prophylaxis
NICE (2007, updated 2017)	Atypical, < 6/12 age	No unless <6 months of age with positive US or atypical UTI	Yes >6/12 post UTI	No
AAP (2011)	Yes	No unless abnormal US	No	No
ISPN (2020)	Yes	No unless abnormal US or bacteria other than UPEC	Consider if major abnormalities at US	Considered for VUR IV-V
CARI (2014)	Yes, if: No second or third trimester US, <3/12 age, or atypical UTI	No unless abnormal US	No	No
Canadian (2014)	Yes	No unless abnormal US	No	No

Renal Scintigraphy

Renal imaging with a radionucleotide dimercaptosuccinic acid (DMSA) scan is useful in assessing renal morphology and function, producing static images. The test entails the intravenous administration of a radioactive isotope that localizes to the renal parenchyma. Decreased uptake of isotope as seen on a gamma camera several hours postinjection can confirm pyelonephritis if performed within 1 week following a febrile UTI or determine if scarring has resulted if undertaken 6–12 months later. Delaying the test to diagnose a renal scar is important as uptake defects from pyelonephritis can persist for several months. The DMSA scan can also differentiate congenital renal hypodysplasia from acquired scarring that may otherwise be difficult to discern. The former typically appears as a smaller kidney with uniform uptake of isotope, while the latter usually manifests as a focal uptake defect with disruption of the normally smooth kidney contour.

The AAP guidelines make no recommendation regarding an "early" or "late" DMSA scan following a febrile UTI [46], NICE guidelines recommended a late DMSA scan when the infection is atypical [67], and the ISPN does where high-grade VUR is present (Table 3) [47]. An alternative promoted by some is the "top-down" approach whereby a DMSA scan is performed as an initial investigation in the acute phase of the illness, followed by VCUG if the scan is positive. Two studies reported a strong correlation between abnormal DMSA scans and high-grade VUR. In contrast a more recent study demonstrated a normal DMSA scan during the acute infection in 14/46 children with grade III–IV reflux [84]. A late DMSA scan has been recommended by some, in order to detect those children with renal scarring that require follow-up [73, 85]. DMSA scans are not indicated in patients that have afebrile UTIs.

Two other isotopes that are useful for renal nuclear medicine imaging include technetium-99 m-labeled diethylenetriaminepentaacetic acid (DTPA) and technetium-99 m-mercaptoacetyltriglycine (MAG3). Both have a dynamic early excretory phase that is useful for determining the existence and severity of obstruction, when dilatation of the urinary tract is noted on a structural imaging study such as ultrasound. ^{9m}TC-MAG3 renal scintigraphy has also been used in indirect cystography but has low sensitivity in detecting VUR of any grade and cannot, therefore, be proposed as an alternative to VCUG in the diagnosis of VUR (or for posterior urethral valves) [86].

Other Imaging Modalities

Intravenous pyelography has been virtually completely replaced by KBUS and radionuclide scintigraphy. Magnetic resonance urography (MRU) allows for the precise evaluation of anatomical features and less so functional imaging while avoiding radiation exposure. MRU has limited capacity to evaluate obstruction, i.e., measuring cortical transit times of contrast media. Currently no guidelines recommend MRU due to the need to sedate the child. With further development of the technology, MRU may become more cost-effective and a viable alternative to currently used imaging modalities [87].

Antibiotic Prophylaxis

Long-term low-dose prophylactic antibiotics administered following an uncomplicated first febrile UTI have been shown in prospective studies to be of minimal or no value in the prevention of breakthrough UTIs or subsequent risk of scarring. In the past, antibiotic prophylaxis had been extensively prescribed following pyelonephritis, mainly in the presence of VUR, on the unproven hypothesis that it reduces UTIs and avoids kidney scarring [88]. Eight prospective randomized controlled trials (2390 children) evaluated the effectiveness of prophylaxis [89, 90, 91, 92, 93, 94, 95, 96]. Given the disparate populations, duration of follow-up, and investigations performed, it is difficult to compare the studies directly; however, some conclusions are possible. Recurrent UTI was the primary endpoint in all papers. Antibiotic prophylaxis showed no benefit compared to no treatment in four studies evaluating children with absent or mainly low-grade VUR [89, 90, 91, 92]. The Swedish Reflux Trial, conducted in 203 infants with grade III–IV reflux, reported a reduction in febrile UTIs on prophylaxis compared with controls (19% vs 57%, $p < 0.001$) over a 2-year period in girls, but not boys [94]. The two largest placebo-controlled studies, the PRIVENT (576 children, 64% female, 61% absent or grade I–II VUR) and RIVUR (607 children, 92% female, 92% grade I–III VUR) trials, enrolled 1183 children with a significant reduction in breakthrough UTIs in the antibiotic prophylaxis arm. This result is statistically significant, although some believe less clinically relevant, given the need of 14–16 patient years of prophylaxis to prevent one symptomatic UTI and 22 patient years of treatment to prevent one febrile UTI [93, 95]. The benefit of prophylaxis was seen predominantly in the initial 6 months, in both papers. The RIVUR study showed that the largest benefit for reduction of subsequent UTI with prophylaxis was in patients with bowel and bladder dysfunction. Overall, a systematic review of these two studies demonstrated a slight benefit of prophylaxis in reduction of recurrent UTI, at the same time as an increase in bacterial resistance. The severity of VUR and the appearance of scarring were not addressed [97].

The risk of renal scarring was evaluated with a late DMSA scan in seven of the previous studies. Only the Swedish Reflux Trial showed a reduction of scarring in female infants with high-grade VUR, on prophylaxis [81]. Importantly, no single study had adequate power to demonstrate a benefit of prophylaxis in regard to renal scarring. Furthermore, a systematic review and meta-analysis of 1427 subjects from the previous seven RCTs was unable to show that antibiotic prophylaxis prevented renal scarring, as did a sub-analysis restricted to the 1004 subjects with vesicoureteral reflux [98]. A shortcoming of these trials relates to the populations enrolled, as many had absent or low-grade reflux and the majority were female (92% in the RIVUR study) and these patients are expected to have a good outcome regardless of intervention. The population at risk for progressive kidney disease, males with high-grade VUR, often in association with renal (hypo)dysplasia and bladder issues, were underrepresented and frequently excluded by enrolment criteria.

Various guidelines no longer support routine antibiotic prophylaxis in children with VUR (Table 3). In children with recurrent febrile UTIs and grade IV–V reflux, for whom prophylaxis might be beneficial, there is little agreement regarding the duration of the prophylaxis. One approach is to consider 2 years in females and 1 year in male infants who have recurrent febrile UTIs and high-grade reflux. Nitrofurantoin is an appropriate first-line agent, although side effects and risk of poor adherence often preclude its use. Cotrimoxazole or amoxicillin/clavulanate are often preferred.

Antibiotic Prophylaxis and Risk of UTIs in Different Urological Disorders

Major urological malformations particularly those involving the bladder commonly predispose to UTI. Persistent bladder dysfunction can be seen with a range of disorders such as posterior urethral valves, neurogenic bladder, and bladder exstrophy, each often managed with clean intermittent catheterization, and as such pose risks for bacterial colonization of the bladder and recurrent UTIs. These children are no longer treated with antibiotic prophylaxis; the one randomized controlled trial on clean intermittent catheterization in children demonstrated a significantly higher incidence of UTIs in the prophylaxis arm compared with those with no treatment [99]. In addition, a meta-analysis examining the use of antibiotic prophylaxis in older children and adults with spinal cord dysfunction did not support prophylaxis [100]. Even with these data, there is considerable disagreement in how to best manage patients with persistent bladder dysfunction.

One report showed that avirulent commensal organisms frequently colonize neurogenic bladders in children [101]. These organisms did not appear to cause symptomatic UTI or decline in kidney function, despite prolonged colonization. Thus, asymptomatic bacteriuria in this population does not warrant treatment.

The role of antibiotic prophylaxis in infants and young children with high-grade VUR and chronic renal insufficiency due to (hypo)dysplasia, who are at high risk of deteriorating renal function, has not been evaluated in a prospective controlled trial. A particularly vulnerable population are newborns, who have not experienced a UTI, but that were diagnosed with congenital renal abnormalities on prenatal US. An international multicenter randomized controlled trial (PREDICT trial) to evaluate prophylaxis in the above population has completed enrollment, with the final results expected at the end of 2021 (ClinicalTrials.gov Identifier: NCT02021006).

Additional Strategies to Prevent UTI

Circumcision

Circumcision for the prevention of UTIs has not been evaluated in prospective randomized trials [102]. Two systematic reviews of manly cohort studies reached conflicting outcomes. In the first, routine circumcision was not recommended in normal boys, as the number needed to treat was calculated as 111 to prevent 1 UTI. The authors suggested that it could be an option when recurrent UTIs or high-grade reflux are present [103]. In the second, circumcision was recommended in all boys, as it reduced the lifetime risk of UTI, with approximately four circumcisions to prevent one UTI [104].

Cranberry

Consumption of cranberries (or cranberry juice) has been reported to inhibit the adhesion of UPEC to the endothelial cells of the urinary tract and thus be of possible benefit in reducing UTIs. A Cochrane review of 24 trials, however, did not show a benefit of cranberry consumption in the prevention of recurrent UTI. The trials were undertaken in a variety of clinical settings, including in patients with neuropathic bladders and/or spinal injury [105].

Probiotics

Probiotics have been proposed as a possible means of reducing recurrent UTIs. Most studies have been performed in women rather than children using different strains of organisms (predominantly lactobacilli), and results are conflicting [106]. One study showed a slight benefit in prevention of UTIs using probiotic prophylaxis over a 6-month period [107]. The paper had methodologic weaknesses that preclude widespread recommendations regarding probiotic use.

Constipation

Constipation has long been recognized as a risk factor for recurrent UTIs. One study of 234 chronic children with constipation, wetting issues, and infections demonstrated that successful treatment of the constipation resulted in cessation of diurnal enuresis in 89%, nocturnal enuresis in 63%, and UTI in all [108]. The treatment of constipation and soiling in "at-risk" children is clearly important in the prevention of recurrent UTIs (see Bladder Disorders, Chap. 59).

Surgical Correction of Vesicoureteral Reflux

Surgical correction of reflux, a common procedure in the past, is no longer routinely recommended. The surgery may be considered in patients with breakthrough febrile UTIs despite prophylaxis, particularly in association with high-grade reflux in females (see Vesicoureteral Reflux, Chap. 59).

Future Clinical UTI Sequelae

Most uncomplicated UTIs have limited long-term outcomes. Febrile UTIs have a high likelihood of inflammation at the renal parenchymal level, leading to possible renal scarring, which may be responsible for long-term adverse events. Without scarring, long-term issues are typically absent. Overall, renal scarring following a febrile UTI has been reported with a prevalence of 15% in a systematic review [109] and appears unrelated to age [110]. A meta-analysis of 9 studies involving 1280 children and adolescents showed that scars developed in 191 children; those with the highest rates included those with fever >39 °C and ultrasound abnormalities, in whom the causative organism was not UPEC [111]. Conflicting views exist regarding the relation between the magnitude of scarring and potential long-term adverse outcomes.

Widespread use of antenatal ultrasound over the past several years has shown that renal parenchymal damage previously attributed to pyelonephritis is usually the consequence of congenital maldevelopment of the kidneys. This maldevelopment is frequently accompanied by anomalies of the lower urinary tract, including high-grade VUR and/or obstruction. Long-term sequelae of concern include hypertension, pre-eclampsia, and chronic kidney disease. A comprehensive review highlighted the finding that older studies, predominantly retrospective from biased populations, recorded a high incidence of adverse outcomes [112]. More recent publications that are population based and/or that exclude congenital renal disease by prenatal ultrasound report a much lower incidence of harmful sequelae. Only 0.4% of 1029 children recruited in prospective trials with normal renal function at the outset reported significant declines on follow-up. The vast majority of children with impaired renal function at the end of follow-up had had scarring or renal dysplasia at the time of enrollment. The same review evaluated 713 children from 5 studies and found that the incidence of hypertension increased from 2.4% to 4.6% during 5 to 20 years of follow-up [113, 114, 115, 116, 117]. Those studies showing a high incidence of hypertension, scarring, and renal damage in patients at follow-up were in those patients where these findings were present at study onset. One study with a follow-up of 16–26 years, evaluating 53 children with scars and 51 without after a first UTI, was unable to show any difference in blood pressure profiles by ambulatory blood pressure monitoring between the two groups [118].

Regarding pregnancy complications, 1 study evaluated 72 women (median age of 41) who had given birth and who had a prior history of childhood UTI and found an overall low complication rate. Hypertension was diagnosed in 10 out of 151 pregnancies and preeclampsia in 4, all in women with renal damage. All women were normotensive before their first pregnancy [119]. While this prospective study is limited, it does provide reassuring long-term data on effects of childhood UTI on later complications.

Conclusions

UTI is a common problem in pediatric and adolescent patients. One of the clinical challenges of diagnosing a UTI includes possible vague presenting symptoms, especially in young children. Thus, a high index of suspicion is appropriate when a young child presents for evaluation with fever without other explanation. Although the gold standard to diagnose a UTI is a urine culture, clinicians routinely rely upon their clinical suspicion and the results from a urine dipstick test to decide on whether to initiate therapy. Oral antibiotic therapy for febrile UTI in young children should last 7–14 days and be modified if necessary based on the urine culture results. The appropriate work-up after a UTI in infants, children with an atypical UTI, or lack of prenatal imaging often includes a KBUS. Children with renal scarring after a UTI should be followed long term for possible hypertension and/or chronic kidney disease.

Abstract

Vesicoureteral reflux (VUR) is the most common congenital anomaly of the urinary tract in children. Primary VUR is diagnosed mostly after a urinary tract infection (UTI). It is also diagnosed during postnatal evaluation of antenatally diagnosed hydronephrosis or other congenital anomalies of the kidney and urinary tract (CAKUT). High-grade VUR ($\geq$ grade 3) is a risk factor for acute pyelonephritis-associated acquired reflux nephropathy. Other important risk factors for reflux nephropathy include recurrent UTIs and a delay in initiation of antibiotic treatment. Not all children with a first febrile UTI need a voiding cystourethrogram (VCUG), but it should be considered in those with abnormal ultrasound findings, recurrent UTIs, and/or an atypical causative pathogen. The management of VUR depends on multiple factors and may include surveillance only or antimicrobial prophylaxis; very few patients with VUR need surgical correction. Patients with reflux nephropathy should be monitored for hypertension and those with significant bilateral scarring should be monitored for proteinuria and chronic kidney disease.

Introduction

Vesicoureteral reflux (VUR) may be primary or secondary. Primary VUR is the most common congenital anomaly of the urinary tract and is usually diagnosed after UTI or during follow-up of antenatally diagnosed hydronephrosis (see ▶ Chap. 55, "Urinary Tract Infections in Children"). In contrast, secondary VUR typically develops after a surgical procedure such as a renal transplant, decompression of a ureterocele, correction of vesicoureteral junction obstruction, or due to increased bladder pressure. Increased bladder pressure may occur due to anatomical obstruction caused by posterior urethral valves or urethral or meatal stenosis (see ▶ Chap. 57, "Pediatric Obstructive Uropathy") or a functional bladder abnormality as seen with neurogenic bladder, nonneurogenic neurogenic bladder (Hinman's syndrome), and Ochoa syndrome (see ▶ Chap. 58, "Bladder Disorders"). Transient VUR may occur in patients with bladder bowel dysfunction or bladder infection. In this chapter, we will discuss primary VUR because it is the most common type diagnosed in otherwise healthy children.

Incidence and Prevalence

The exact incidence of primary VUR is not known because it is not feasible to do a VCUG in a large cohort of healthy children. Its reported prevalence varies from 1.3% of healthy children to anywhere from 8% to 50% of children evaluated after UTI [1]. In newborns and infants, the incidence of VUR diagnosed after UTI is 36–49% [1]. Children with VUR detected after UTI are predominantly females [2, 3]. VUR diagnosed during follow-up of antenatally diagnosed hydronephrosis is seen more often in males [4]. VUR is less common in African American children and typically less severe as compared to Caucasian children [5]. Eighty-one percent of the 607 patients in the Randomized Intervention in Children with VUR (RIVUR) study were Caucasian [6].

Embryology and Anatomy

The ureterovesical junction is designed to prevent backflow of urine from bladder to the kidney. The ureters pass obliquely into the bladder through the detrusor. The distal end of the ureter is located submucosally within the bladder and when the submucosal tunnel is short, this can predispose to VUR. The muscle fibers of the ureter extend into the trigone of the bladder and are interwoven with the fibers from the opposite ureter. The intermingling of fibers allows fixation of the ureters within the trigone of the bladder. While no true valve exists at the ureter-bladder junction, the distal submucosal ureteral segment compresses against the muscular bladder wall during bladder filling, occluding the ureteral orifice and preventing the reflux of urine. Finally, the tone of the ureter and the anatomical location of the ureteral orifice within the trigone also prevent reflux.

The ureteric bud is an embryonic primordial structure that gives rise to the final metanephric kidney and the ureter (see ▶ Chap. 1, "Pre-natal Development of the Kidneys and Urinary Tract"). The precise location of where the ureteric bud emerges is critical to the formation of the kidney and the ureter since both tissues require the correct milieu of transcription factors and signaling molecules for their development. If the ureteric bud emerges from a more caudal location along the mesonephric duct, the kidney that forms may lack the proper complement of nephrons and/or even exhibit signs of dysplasia [7]. In addition, the final location of the ureteral orifice may not be within the trigone, but in a more lateral and proximal location. The abnormally located orifice arises with a shortened submucosal ureteral tunnel that is predisposed to VUR. Indeed, the shared embryonic origin of the kidneys and ureters is one explanation for the co-occurrence of VUR and renal dysplasia or congenital reflux nephropathy that is typically observed in boys (see ▶ Chap. 3, "Congenital Anomalies of the Kidneys").

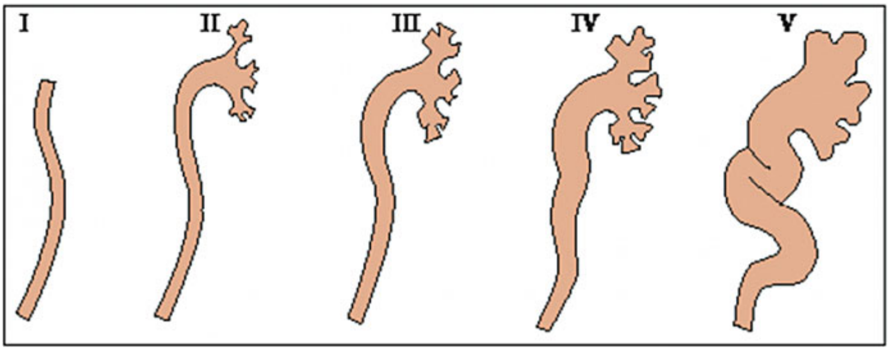

Fig. 1 International grading **system for vesicoureteral reflux** (International Reflux Study grading scheme. Grade I – reflux into non-dilated ureter. Grade II – reflux into the renal pelvis and calyces without dilatation. Grade III – mild/moderate dilatation of ureter and pelvicalyceal system. Grade IV – dilation of the renal pelvis and calyces with moderate ureteral tortuosity, blunting of fornicies. Grade V – gross dilatation of the ureter, pelvis, and calyces; ureteral tortuosity; loss of papillary impressions)

Grading of VUR

The gold standard for diagnosing VUR is a voiding cystourethrogram (VCUG). VUR is classified into 5 grades (Fig. 1). Grade I is reflux into the ureter, grade II is reflux into the renal pelvis without any dilation of the calyces, grade III is reflux to the renal pelvis with mild dilation of the renal pelvis, grade IV is reflux to the renal pelvis with greater dilation of the renal pelvis, and grade V is reflux to the renal pelvis with ureteral and pelvic dilation. The RIVUR study revealed that there is a considerable inter-observer variability in the VUR grading by a VCUG. Radiologists varied by one grade in about 20% of patients and rarely by two or more grades [8].

Radionuclide voiding cystogram has also been used to diagnose and follow children with VUR. However, using this modality, reflux can only be graded into mild, moderate, and severe as the resolution is not as good as with a contrast VCUG.

Natural History of VUR

Primary VUR generally improves with time, and this is attributed to the lengthening of the submucosal segment of the ureter with overall growth of the body. Other factors associated with resolution of VUR include low grade at diagnosis, nonwhite race, and the absence of bladder bowel dysfunction [9]. In one study, the mean time until spontaneous resolution in black children was 14.6 months, which was significantly shorter than the mean of 21.4 months in white children [10]. Unilateral VUR has a better probability of resolution as compared to bilateral VUR. One study in 735 children with primary VUR examined the median time for persistence of reflux over a follow-up period between 6 and 411 months; the authors found median resolution times of 38 months for grade I/II, 98 months for grade III, and 156 months for grade IV/V VUR [11]. The rate of resolution of VUR may be higher in younger children. In a 5 year follow-up study in children less than 5 years old, grade I VUR resolved in 82%, grade II in 80%, and grade III in 46% of the ureters [12]. The rate of resolution is better in nondilated as compared to dilated ureters. Schwab and colleagues reported that grades I-III VUR resolve at a rate of 13% per year for the first 5 years of follow-up and 3.5% per year during subsequent years; moreover, grades IV and V VUR resolve at a rate of 5% per year [13].

Clinical Presentation of Primary VUR

Primary VUR is often diagnosed in one of three ways – following UTI, during follow-up for congenital abnormalities of the kidney and urinary tract (CAKUT)/antenatal hydronephrosis, or while screening a sibling of a patient with VUR.

UTI and VUR

UTI, particularly in younger children, is the most common presentation that leads to the diagnosis of VUR. In a large cohort of children with UTI, VUR was diagnosed in 46% of infants and 9% of preschool children [14]. The majority of children with VUR diagnosed after a UTI are girls, although when considering infants <6 months of age, no gender difference is noted [15].

CAKUT/Antenatal Hydronephrosis and VUR

VUR is the most common abnormality observed in children with CAKUT [1]. In children with prenatal hydronephrosis, postnatal evaluation with VCUG reveals the presence of VUR in 10–30% of infants [16]. However, as is the case with UTI, the number of VCUG tests requested for this indication has also been decreasing over time. The incidence of VUR is higher in boys with antenatal hydronephrosis [4]. VUR associated with antenatal hydronephrosis has a high rate of spontaneous resolution (59% by age 4 years) even in those with grades IV–V reflux [17]. Uncircumcised male infants with prenatal hydronephrosis and VUR have a significantly higher incidence of UTI even in those prescribed antibiotic prophylaxis [18].

Siblings and VUR

A study showed that 66% of children that had a parent with VUR also had VUR indicating a significant parent to child transmission [19]. Studies by Jerkins and Noe revealed that 32% of siblings of index children with VUR also had VUR [20]. Review of the natural history of VUR in siblings indicated that 52% had resolution of reflux after 18 months of follow-up, with yearly resolution rates of 28% [21]. A more "benign" course of "sibling reflux" compared to reflux identified after a UTI [22] has led many to question the usefulness of screening of asymptomatic siblings. Currently, no routine screening for siblings of a diagnosed child with VUR is advised unless the sibling develops a UTI.

Bladder Bowel Dysfunction

VUR may be associated with bladder bowel dysfunction (BBD) which is also called voiding dysfunction or dysfunctional elimination syndrome (see ▶ Chap. 58, "Bladder Disorders"). The exact pathogenesis of BBD is not known. It appears to occur from difficulties with toilet training, evolving from poorly learned voiding technique in which the child attempts to suppress impending or active bladder contractions by inappropriately contracting the pelvic floor muscles and tightening the external sphincter [23]. This results in increased bladder pressure and/or inefficient bladder emptying [24]. Bladder dysfunction is invariably associated with constipation. BBD can be assessed using a questionnaire called the dysfunctional voiding scoring system [25]. The symptoms of BBD include daytime wetness, urgency, frequency, infrequency, recurrent UTI, dysuria, abdominal pain, constipation, and/or fecal incontinence in "toilet trained" children with no underlying anatomic or neurological abnormality.

In a study of 366 children with symptoms of BBD, 77% of the patients were females and the mean age at referral was 8.5 years (range, 4–18 years). Constipation/encopresis was reported in 30% cases, day-time wetting in 89%, night-wetting in 79%, and recurrent UTI in 60% of the patients. VUR was present in 20% of the patients who underwent cystourethrography [26]. In the RIVUR study, using the dysfunctional voiding scoring system [25], BBD was identified in 56% of 126 toilet-trained children (<6 years of age) with grade I to IV VUR [6].

BBD predisposes to recurrent UTI, induces and perpetuates VUR, and may result in permanent renal damage. BBD increases the risk of febrile UTI in children with VUR on antimicrobial prophylaxis (44% with BBD and 3% without

BBD) and it delays VUR resolution at 24 months (31% with BBD and 61% without BBD) [27]. The frequency of postoperative UTI is greater in children with BBD (22%) compared to those without BBD (5%) [27]. BBD can also adversely affect the results of ureteric reimplantation [28]. The frequency of UTI after open or endoscopic surgical correction of VUR is greater in children with BBD (22%) compared to those without BBD (5%) [27]. In summary, BBD is a relative contraindication for surgical correction of VUR because of a higher likelihood of treatment failure and the potential for recurrent UTI [27].

BBD is a diagnosis of exclusion that mandates a detailed history and physical examination to rule out any underlying neurological or neuromuscular etiology. Urinalysis, bladder ultrasound, and VCUG in selected cases are helpful in making a diagnosis. The role of full urodynamic studies with catherization is not well-established, in part because study results are not consistent. The procedure is invasive and the results may not change therapy or influence the final outcome. However, evaluation of the bladder with a postvoid residual and assessment of the urine flow can be useful in the evaluation of BBD related to VUR. Multidisciplinary management of BBD with dedicated pediatric nurses and a psychologist facilitated the resolution of VUR in 53% of patients after a mean follow-up period of 22 months [26].

Constipation is an invariable part of BBD, but may be an isolated finding, which alone increases the risk of recurrent UTI in children with VUR. Constipation causes compression of the bladder and the bladder neck secondary to stool in the colon. The fecal load increases the bladder storage pressure and the residual urine volume postvoid. Also, the distended colon and/or soiling provide an abundant reservoir of pathogens, which may affect the profile of the stool microbiome and increase the diversity of species [29–31]. Constipation in children increases the likelihood of urinary incontinence, bladder overactivity, dyscoordinated voiding, recurrent UTI, and persistence of VUR [31].

VUR and Renal Scarring

In 1960, Hodson and Edwards described the co-occurrence of VUR with chronic pyelonephritis [32], which subsequently came to be known as reflux nephropathy (RN) [33]. Pyelonephritis-induced renal injury in the presence of VUR is called acquired RN. This differentiates it from congenital RN, which is a result of abnormal renal development and not secondary to injury from pyelonephritis. Congenital RN is more common in boys, whereas acquired RN due to febrile UTI is more common in girls [34]. Some other important differences between acquired and congenital RN are shown in Table 1 [35]. In previous studies on reflux nephropathy, inclusion of patients with preexisting renal injury without clinical pyelonephritis may have falsely increased the number of patients reported to have acquired RN. In more recent randomized studies, renal scarring correlated with gender, with males demonstrating more renal scarring. This could be attributed to the higher incidence of congenital RN observed in boys [36].

The gold standard for diagnosing RN is dimercaptosuccinic acid scintigraphy (^{99m}Tc-DMSA). The DMSA renal scan does not differentiate between congenital and acquired RN, which may look similar on imaging. The DMSA

Table 1 Congenital versus acquired reflux nephropathy in children (Modified from Mattoo TK [35])

	Acquired reflux nephropathy	Congenital reflux nephropathy
Time of occurrence	Postnatal	Prenatal
History of UTI before diagnosis	Common	Uncommon
Age distribution	All pediatric age groups	Mostly in younger children
Gender distribution	Predominately females	Predominately males
Grade of VUR at the time of diagnosis	Variable depending on age	Mostly high grade
Renal histology	Chronic inflammatory changes	Features of renal dysplasia

UTI: Urinary tract infection, VUR: Vesicoureteral reflux scan should be performed at least 4–6 months post-UTI. This allows the acute inflammatory reaction associated with pyelonephritis to subside, at which point any persistent cortical defects can be assumed to represent permanent renal scarring. However, in the absence of a baseline (pre-acute pyelonephritis) scan, it may be difficult to differentiate acquired from congenital lesions.

The reported prevalence of renal scarring after febrile UTI is about 15% [37]. Scarring ranges from 3% after the first UTI to 29% after more than three febrile UTIs [38, 39]. Renal scarring occurs with acute pyelonephritis with or without VUR, but the risk is higher in the presence of VUR. The role of VUR in renal scarring has been reported in multiple clinical studies and has been shown to be causally linked to scarring in a pig model [40].

Mechanism of Renal Injury

Several studies have shown that scarring develops at the same sites where bacteria infect the renal parenchyma. Renal scarring due to intrarenal reflux, that is, when urine refluxes from the renal pelvis into the calyces, occurs mostly at the renal poles. Morphologic evaluation demonstrates that extensively fused (compound) papillae are associated with intrarenal reflux and occur almost exclusively at the upper and lower poles of the kidney [41]. Renal scarring may result from a single episode of pyelonephritis, especially in young children, also known as the "big bang effect" [42] or the process may take several years. After acute pyelonephritis, renal scarring can take months to be detected on a DMSA renal scan [43].

The exact pathogenesis of renal scarring following acute pyelonephritis is not well understood, but from animal models, it is clear that inflammation is central to the development of a renal scar. The innate immune response of the urinary tract refers to immediate host responses which clear the bacterial infection. The innate immune response includes recognition of bacteria via specific pathogen recognition receptors located on uroepithelial cells, the Toll-like receptors (TLRs), recruitment of neutrophils, and production of proinflammatory cytokines like interleukin (IL)-8 and IL-6 [44, 45] (see ▶ Chap. 55, "Urinary Tract Infections in Children"). Uroepithelial cells express TLR4 which senses lipopolysaccharides in the cell wall of Gram-negative bacteria like *E. coli* and activates a signaling cascade resulting in the release of IL-8. This, in turn, recruits neutrophils and other inflammatory cells from the bloodstream into the urinary tract [46, 47]. This rapid neutrophil response is essential for clearing a urinary tract infection and is largely driven by IL-8 signaling through its receptor, IL-8R.

According to Roberts and colleagues, the acute inflammatory response that eradicates the invading bacteria also appears responsible for early renal parenchymal damage and subsequent scarring [48]. The early release of IL-6 and IL-8 is a chemoattractant for leukocytes that migrate to the site of infection where they exert a microbicidal effect through phagocytosis. During phagocytosis, neutrophils and monocytes release lysosomal enzymes and superoxides, to ingest the invading bacteria. The inflammatory response is also accompanied by tubular ischemia and reperfusion injury. Antioxidant-mediated renal tubular injury is attributed to the release of superoxides during tissue reperfusion [49, 50]. The fibrosis that follows is initiated mainly by activated fibroblasts or myofibroblasts that secrete collagen. Myofibroblasts may possibly arise from differentiation of tubular epithelial cells to fibroblasts, epithelial-mesenchymal transition (EMT), from endothelial to fibroblast differentiation as part of endothelial-mesenchymal transition, from proliferation of local fibroblasts and pericytes or as part of a macrophage to myofibroblast transition [51]. Cytokines produced as part of inflammation include transforming growth factor-beta 1, platelet-derived growth factor, and fibroblast growth factor, which attract and stimulate the proliferation of fibroblasts that are ultimately responsible for collagen production and scarring. Explanations for progressive parenchymal renal injury even after VUR has ceased include hyperfiltration of intact nephrons, the presence of Tamm-Horsfall protein in the interstitium as a putative antigenic determinant, superoxide production, and persistent hypertension. Hyperfiltration of intact nephrons causes glomerulosclerosis, activation of the renin-angiotensin system, and a gradual deterioration of renal function [52, 53].

Risk Factors for Renal Scarring

A number of risk factors are associated with acquired renal scarring. These include recurrent UTI, high grade VUR, duration of fever of > 72 h prior to antibiotic initiation, and organisms other than *E. coli*. There is also evidence that genetic risk factors predispose children with VUR to renal scarring.

Recurrent UTI

Recurrent UTI is a well-known risk factor for renal scarring [36, 54]. In the RIVUR study, children with a second UTI had significantly more renal scars [OR], 2.85; 95% confidence interval [95% CI], 1.38 to 5.92) as compared to those with a single UTI [36]. A post hoc analysis of RIVUR and CUTIE [Careful Urinary Tract Infection Evaluation] studies revealed that the odds of renal scarring after a second febrile UTI was 11.8 (95% CI, 4.1–34.4) times greater than after a single febrile infection and the odds of renal scarring after three or more febrile infections was 13.7 (95% CI, 3.4–54.4) times greater than after a single febrile infection [55].

Vesicoureteral Reflux

High-grade VUR, grade III or higher, is an important risk factor for renal scarring. Children with high-grade VUR are more likely to develop scarring than children with lower grades (RR: 2.1 [95% CI: 1.4–3.2]) [56]. The odds ratio of renal scarring with acute pyelonephritis in the presence of VUR versus no VUR is 2.8 for patients and 3.7 for renal units [27]. Another systematic review reported that children with VUR have a greater likelihood of developing acute pyelonephritis and renal scarring than children without VUR [56]. A meta-analysis of the published data revealed that renal damage (per 100 renal units) occurred in 6.2% in those with grades I–III VUR and 47.9% in those with grades IV and V VUR [57]. In the RIVUR study, the proportion of new scars in renal units with grade 4 VUR was significantly higher than in units with no VUR (OR, 24.2; 95% CI, 6.4 to 91.2) [36].

Delay in Treatment

Delay in the treatment of febrile UTI increases the risk of renal injury. A multivariate analysis of 158 children with febrile UTI showed that a delay of greater than 48 h in the initiation of antibiotic treatment was associated with an increased risk of acute lesions on renal scan [58]. The RIVUR study revealed that delayed initiation of antibiotic treatment was associated with an increased risk of scarring, with the odds ratio of new renal scarring 74% lower among children whose treatment started within 24 h of onset of fever, compared to those whose treatment started after 72 h of fever [55]. Young children with pyelonephritis also have higher rates of other complications such as sepsis and abscess formation when treatment is delayed.

Patient Age

Recent studies have shown that young age may not be a risk factor and that older children may be at a higher risk of renal scarring [36–38]. In the past, young age was thought to be a risk factor likely due to the inadvertent inclusion of patients with preexisting congenital scarring (renal dysplasia). Renal scarring occurs in adult kidneys as well, as is seen in adult transplanted kidneys [59]. Also, adult pig kidneys with VUR and UTI scar as quickly/easily as those of piglets [60].

Complications of Renal Scarring

The complications of renal scarring are well known, but poorly defined because of their insidious onset, slow progression, and the lack of well-designed prospective studies in children as well as in adults. Hypertension and proteinuria are the most common complications. Other complications include focal segmental glomerulosclerosis (FSGS), urinary concentration defects, hyperkalemia, and acidosis [61, 62]. In most children, renal scarring may not be clinically significant [63].

Proteinuria

Renal parenchymal injury may cause persistent proteinuria, which may lead to nephrotic syndrome in some cases. Overt proteinuria, which has been reported in 21% of adult patients with RN [64], is rare in pediatric patients. The pathogenesis of proteinuria in RN is not well understood and is attributed to immunologic injury, macromolecular trapping and mesangial dysfunction, vascular alterations and hypertension, and glomerular hyperfiltration. Of these explanations, the one that seems most plausible is hyperfiltration in remnant nephrons. This results in modifications in selective permeability to macromolecules such as albumin and progression of renal disease [65, 66]. The histologic hallmark in such patients is hypertrophy of surviving nephrons with focal and segmental glomerulosclerosis [67]. FSGS is progressive and can occur in nonscarred parts of the kidney or in the normal contralateral kidney in patients with unilateral RN [61].

Microalbuminuria, which indicates glomerular damage at a very early stage, precedes the development of overt proteinuria, progressive renal damage, and renal failure. Microalbuminuria has been reported in 51% of pediatric patients (mean age 9.8 + 4.2 years) with renal scarring [68] and increases with the severity of renal scarring [69, 70].

Hypertension

Hypertension occurs in 10–30% of children and young adults with renal scarring [71, 72] and 34–38% of adult patients with renal scarring [64, 73]. In adults, confounding factors such as renal scarring due to renal stones and other renal pathologies make interpretation difficult. In a study involving 664 patients diagnosed with VUR between 1970 and 2004, 3% of patients developed hypertension. The estimated probability of hypertension was 2%, 6%, and 15% at 10, 15, and 21 years of age, respectively. The survival analysis revealed that about 50% of children with unilateral and bilateral renal damage develop persistent hypertension at about 30 and 22 years of age, respectively [74]. In a follow-up period lasting 15 years in pediatric patients with renal scarring, about 13% of patients at age 20–31 years were hypertensive [75].

The exact cause for hypertension due to renal scarring is not known, but is believed to be due to segmental ischemia with increased renin secretion. It does not depend on the severity of renal scarring. In a 5-year prospective study of patients with longstanding reflux nephropathy, there was no correlation between blood pressure (BP) and plasma renin activity (PRA), plasma creatinine concentration, or the degree of scarring [76].

Some studies have reported no increase in BP after many years of follow-up. In a study of 146 subjects with VUR diagnosed at a mean age of 5 years, no hypertension was seen after a mean follow-up of about 10 years. The cohort included 34.3% patients with renal scarring [77]. In another study of 53 patients with renal scarring following childhood UTI, there was no significant difference in ambulatory BP measurements (ABPM) 16–26 years later, compared to 47 matched subjects without scarring [63]. However, in a follow-up study in 86 adult women (median age 41 years) with UTI in childhood, 24-h ABPM was used to diagnose hypertension. The mean 24-h systolic, mean daytime systolic, and mean night-time SBP were significantly higher in women with renal damage compared to those without renal damage [78].

Chronic Kidney Disease (CKD)

RN is the 4th most common cause of renal failure in children with CKD, in children on dialysis, and in children who have received a renal transplant according to the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) reports [79]. In the CKID study of 586 children aged 1–16 years, with an eGFR of 30 to 90 mL/min/1.73m^2, RN was the underlying cause of CKD in 87 (14.8%) patients [80].

In a study that evaluated the clinical course of 735 children with primary VUR between 1970 and 2004, the probability of CKD was reported as 5% at 10 years after diagnosis of VUR; for children diagnosed after 1990, the probability of CKD was only 2%. This suggests that the prognosis for patients diagnosed with VUR may be improving over time [11]. Another study by the same group evaluated independent predictive factors of CKD in children with severe bilateral grades III-V VUR. The authors found that the probability of CKD for patients with bilateral severe reflux was 15% by 10 years after VUR diagnosis. The three variables that were independently associated with CKD were age at diagnosis >24 months [relative risk (RR) = 4.8, 95% confidence interval (95%CI), 1.8–12.7, $P<0.001$], VUR grade V (RR = 3.5, 95%CI, 1.5–7.9, P = 0.002), and bilateral renal damage (RR = 2.86, 95%CI, 1.3–6.1, P = 0.007). In contrast, admission after 1990 was a protective factor (RR = 0.16, 95%CI 0.06–0.43, $P<0.001$). The study concluded that the long-term renal prognosis in patients with bilateral severe reflux is poor [81]. The long-term follow-up of patients with RN who have undergone renal transplantation appears to be good. The Australia and New Zealand Dialysis Registry reported on first kidney transplants performed between 1985 and 2015 in individuals less than 30 years of age with a diagnosis of CAKUT. The 10-year graft survival in individuals with CAKUT was favorable: patients with RN had a 70% graft survival at 10 years and 49% at 20 years [82].

Complications in Adults with VUR Diagnosed in Childhood

The complications of renal scarring are more common in adults, who may present with recurrent UTI, proteinuria, hypertension, and increased serum creatinine. Adult males with RN generally present with hypertension, proteinuria, and renal failure (Table 2). Females present mostly with UTI and pregnancy-related complications [35]. Males have poorer outcomes compared to females. This difference has previously been attributed to a delayed diagnosis in males because of an insidious onset of proteinuria and renal failure. In contrast, the diagnosis may be discovered earlier in females due to recurrent UTI and pregnancy-related complications. However, it is also possible that gender differences in adults may be due to the fact that males are more likely to have congenital RN with renal dysplasia which may lead to greater renal damage than acquired RN, which is seen more in females [35].

In a study of 293 adults with RN (mean age at presentation 31 + 13.4 years), females outnumbered males by a ratio of 5:1. The most common presenting complaints for both genders were UTI (65%), hypertension (20%), and proteinuria (6%). However, UTI as a presenting complaint was significantly more common in females compared to males (72% vs. 31%). In contrast, proteinuria was significantly more common in males (20% vs. 4%). Hypertension was also more common in males than females (29%

Table 2 Reflux nephropathy in adults [35]

	Males	Females
Urinary tract infections	Uncommon	Common
Plasma creatinine	Higher	Normal
End-stage renal failure	More common	Less common
Vesicoureteral reflux	High grade/bilateral	Low grade/unilateral
Proteinuria	Frequent/severe	Infrequent/Less severe
Hypertension	More common	Less common

vs.18%). Although VUR typically resolves over time, VUR was present in 65% of the females and 75% of the males when tested as adults: this suggests the cohort had severe high grade VUR. Of the 147 patients who were followed for a mean period of 6.9 + 3.6 years, 21 (14%) developed ESRD after a mean follow-up of 7.0 + 3.1 years [83]. In a study of 21 adults (mean age 23.9 years) with gross VUR diagnosed in infancy, proteinuria and renal insufficiency was diagnosed in three (23%) of the 13 patients with unilateral reflux nephropathy and two (50%) of the four patients with bilateral reflux nephropathy [84]. In another study of 127 adults (mean age 41 years) with VUR diagnosed during childhood, 44 (35%) had unilateral renal scarring, 30 (24%) had bilateral renal scarring, 30 (24%) had albuminuria, and 14 (11%) had hypertension. Of the 30 patients with bilateral renal scars, 25 (83%) had an abnormal GFR [85].

The potential complications during pregnancy in women with RN include UTI, hypertension, proteinuria, edema, deterioration in renal function, preterm delivery, preeclampsia, and fetal loss [86]. The degree of renal function at conception is associated with the outcome during pregnancy. A review of the literature on the outcome of pregnancy in women with a history of VUR revealed that VUR increases the risk of UTI from 6% to 22%, which increases to 42% when associated with renal scarring. The incidence of hypertension and preeclampsia was significantly higher in women with VUR and renal scarring compared to women with VUR without scarring [86].

Congenital or acquired RN may account for a significant number of adults who commence renal replacement therapy. CAKUT including CAKUT related to VUR leads to end stage kidney disease more often in adulthood than in childhood. In a study of approximately 200,000 patients over 20 years, 2.2% of the patients commenced renal replacement therapy due to a diagnosis of CAKUT. In fact, the median age at renal replacement therapy initiation was 31 years in the CAKUT cohort versus 61 years in the non-CAKUT cohort. CAKUT was diagnosed using ERA-EDTA primary disease codes. The group of patients with VUR and pyelonephritis represented the largest fraction of the CAKUT diagnoses, accounting for 41.9% of the group. Their mean age to commence renal replacement therapy was 38.5 years, indicating that they are developing end stage kidney failure as relatively young adults [87].

Genetics of VUR, UTI, and Renal Scarring

Genetic studies of VUR have been informative to understand the pathogenesis of this disorder and have revealed mutations in genes that are causal for VUR. Some of the limitations of the genetic studies relate to small sample sizes, the clinical variability of study subjects, difficulties in diagnosing asymptomatic carriers especially since VUR may resolve with age, and the impact of environmental factors that may augment phenotypic variability.

From animal models, it is evident that specific gene defects lead to a refluxing uretero-vesical junction. There are also genetic risk factors that predispose to recurrent urinary tract infections and to an impaired host immune response that promotes renal scarring [88, 89]. The first suggestion that primary VUR could be a genetic disorder came from case reports in which monozygotic twins were found to have VUR. Additional support included the fact that VUR frequently affects multiple family members, siblings of children with VUR are more likely to be affected [20, 90], and the fact that there are differences in the incidence of VUR when comparing different ethnic groups [5]. The strongest evidence demonstrating that primary VUR is heritable is a study of 46 twin pairs in which 80% (12/15) of the monozygotic twins had concordant VUR versus 30% (11/31) of the dizygotic twins [91]. When only the youngest affected twin pairs were analyzed, monozygotic twins showed an even higher concordance for VUR at 100% (7/7) versus 50% of the dizygotic twins (5/10). Monozygotic twins are genetically identical and give an estimate of the effect of shared genes, while dizygotic twins give an estimate of the effect of the shared environment. If a disorder shows higher concordance among monozygotic twins versus dizygotic twins, this is strong evidence that a disorder is genetically transmitted.

All genetic inheritance patterns have been reported in primary VUR including monogenic dominant [92, 93], monogenic recessive [94, 95], and complex inheritance when genetic risk factors interact with environmental conditions to predispose to a disorder [96]. A number of genetic approaches have been used to identify genes and loci that are relevant for VUR. This includes genetic analysis of rare patients with VUR and defined chromosomal aberrations. This approach was utilized to identify the *ROBO2* gene as a candidate gene when it was discovered that an individual with a chromosomal translocation that disrupted *ROBO2* also had multiple congenital anomalies including severe bilateral VUR [97]. SLIT2 is a ligand produced by the mesonephric duct. It signals to its receptor ROBO2 that is expressed by the adjacent nephrogenic mesenchyme and together this signaling initiates formation of the ureteric bud [98] (see ▶ Chap. 1, "Prenatal Development of the Kidneys and Urinary Tract"). A number of candidate genes have been sequenced in cohorts of patients with VUR based on their putative roles during kidney/urinary tract development. Some are implicated in the formation of a refluxing uretero-vesical junction, while in other cohorts, the mutations in these same genes have not been identified. Some of these candidate genes include *RET*, a receptor tyrosine kinase expressed by the ureteric bud [99] and *PAX2* a critical transcription factor for kidney and urinary tract development. *PAX2* is associated with a rare syndrome known as renal-coloboma syndrome that also encompasses VUR [100]. Other candidates include the angiotensin type 2 receptor, *AGTR2* [101], and the uroplakin genes, *UPK2* and *UPK3* that are expressed in the uroepithelium of the urinary tract and bladder and affect the morphology of the uretero-vesical junction [102, 103].

Other nonbiased genetic approaches have focused on whole genome-wide mapping of informative families to identify loci and the underlying causal genes. These studies have identified loci on almost every chromosome [95, 104, 105]. Replication studies to validate these loci have generally not been successful, which suggests that primary VUR is genetically heterogeneous. In the largest study to date of 460 families in Europe, parametric linkage analysis using a dominant model revealed linkage to a region on chromosome 10q26 encompassing 69 genes [106]. Gbadegesin et al. using a similar approach performed sequential-wide linkage on a large 97 member family with VUR and joint hypermobility and mapped the disorder to a locus on chromosome 6p [107]. Using whole exome sequencing, they identified a causal heterozygous missense variant in *Tenascin XB*, *TNXB*, a large extracellular matrix protein that regulates collagen deposition. This nonbiased genetic approach to discovery brings a new hypothesis to the understanding of VUR and suggests that perturbations in the extracellular matrix that supports the uretero-vesical junction may predispose to VUR. These observations are particularly compelling since children with VUR frequently demonstrate joint hypermobility [108, 109].

Perturbations in the host immune response can predispose to pyelonephritis and to renal fibrosis. In mice, mutations in *Tlr4* are associated with low-grade chronic pyelonephritis and/or an asymptomatic carrier state known as asymptomatic bacteriuria from failure to initiate the signaling cascade required for neutrophil influx [110–112]. Coding mutations in *TLR4* have not been identified in humans with urinary tract infections, but sequence variation in the *TLR4* promoter is associated with a decrease in TLR4 expression and asymptomatic bacteriuria [113, 114]. Mice bearing a mutation in the IL-8 receptor, *mCxcr2*, can recruit neutrophils to the renal interstitium but the neutrophils are unable to efficiently migrate across the uroepithelium into the urinary tract, leading to acute pyelonephritis and renal fibrosis [115–117]. The findings in the mouse correlate with a human study describing reduced expression of the IL-8 receptor, CXCR1, in a cohort of acute pyelonephritis-prone children [118]. These studies are critical to understanding why some patients with VUR and pyelonephritis never develop reflux nephropathy, while others do. A few candidate genes involved in the host immune response and renal fibrosis have been examined in patients with reflux nephropathy and in patients with acute pyelonephritis. For example, a polymorphism in the Nod-like receptor, *NLRP3*, which senses bacterial pathogens to activate the innate immune response, is associated with acute pyelonephritis in children. A recent study examined copy number variants in children from the RIVUR cohort and found that copy number variants (CNVs) implicated in the innate immune response were enriched in children with VUR compared to age and ethnicity-matched controls [119]. The study of genetic risk factors for UTIs and renal scarring remains an important avenue for future research, which ultimately may lead to new treatments to treat and/or prevent renal scarring.

Diagnosis of VUR and Renal Injury

Ultrasonography

Ultrasonography is the initial modality for the evaluation of postnatal hydronephrosis and UTI in children (see ▶ Chap. 6, "Imaging Kidneys and the Urinary Tract"). It is not a very sensitive imaging modality for the diagnosis of VUR. For example, in the RIVUR study, only 11% of the patients had an abnormal US examination as defined by the presence of hydronephrosis or ureteral duplication [6].

Use of the renal resistive index from color Doppler ultrasound has also been used to follow affected children with VUR, but it has not received widespread acceptance due to its poor correlation with VUR [120]. Color flow Doppler sonography has been used to identify retrograde ureteral jets at the uretero-vesical junction as a sign of VUR. Good correlation was noted with the VCUG [121]; however, the detection of ureteral jets was not sensitive enough to diagnose VUR in all cases. In addition, the child is required to urinate in a supine position, which may be difficult.

Renal US also has very low sensitivity for diagnosing acute pyelonephritis. In one study, US abnormalities compatible with acute pyelonephritis were reported in 20–69% of patients with acute pyelonephritis as compared to 40–92% by DMSA scintigraphy [122]. Nonetheless, a renal ultrasound is useful to diagnose congenital anomalies of kidney and urinary tract and to detect complications of acute pyelonephritis such as renal abscess or pyonephrosis.

Renal ultrasound is also not a sensitive method for diagnosing renal scars. In a study of 159 patients who underwent DMSA renal scan as well as renal US for the evaluation of hypertension of unknown etiology, thirty-three (21%) patients with normal ultrasound examination were found to have renal scars by DMSA. The sensitivity and specificity of renal US, to diagnose renal scars was 36% and 94%, respectively [123].

Voiding Cystourethrogram

VCUG is the primary diagnostic modality for identifying and grading VUR (see ▶ Chap. 6, "Imaging Kidneys and the Urinary Tract"). Concerns that a VCUG performed soon after a UTI would unmask low grades of insignificant reflux have not been borne out by studies to date [124]. The VCUG should be obtained as soon as the child has completed the course of antibiotic therapy for UTI. It should be done selectively in patients with abnormal ultrasound examination, recurrent UTI, UTI with an atypical pathogen, or known renal scarring.

The results of the VCUG can be affected by the size, the type, and the position of the catheter, the rate of bladder filling, the height of the column of contrast media, the state of hydration of the patient, and the volume, temperature, and concentration of the contrast medium. Utilization of sedation to perform the VCUG may compromise the results as children may be unable to void to completion when sedated. The presence and grade of VUR is also affected by the number of times that the bladder is filled during the VCUG. In a study that involved multiple fillings and emptying of the bladder, Jequier reported a discrepancy in the presence and/or grade of VUR from one filling to the other in 12% of patients with two cycles and in 20% of patients with three cycles. No changes were observed with multiple fillings and emptying in cases of grade IV reflux [125]. The aforementioned inter-observer variability in the grading of VUR must be kept in mind when making clinical decisions [8].

The number of VCUG tests done in children on antibiotic prophylaxis for VUR has decreased steadily because of concerns with radiation exposure. However, the current use of low-dose radiographic equipment, including digital fluoroscopy, has reduced radiation exposure [126, 127]. Nuclear cystography has been utilized to reduce the radiation exposure for children during follow-up of VUR. Nuclear cystography, while being more sensitive, does not permit specific grading of VUR and does not reveal anatomical defects such as ureterocele, diverticulum, or the presence of posterior urethral valves. However, it is useful to determine if VUR has resolved after surgical correction.

Technetium 99 m Dimercaptosuccinic Acid Renal Scan (DMSA renal scan)

DMSA is currently the gold standard for diagnosing acute pyelonephritis and renal scarring (see ▶ Chap. 6, “Imaging Kidneys and the Urinary Tract”). Single-photon emission computed tomography (SPECT) DMSA scintigraphy is superior to planar imaging for the detection of renal cortical damage [128, 129]. DMSA scintigraphy is more sensitive than ultrasound, intravenous urography, or CT scan in diagnosing renal scarring [122, 123, 130]. The sensitivity of DMSA scintigraphy in experimentally induced acute pyelonephritis in a pig model was reported to be 92%, when compared to histological findings [131]. The RIVUR study revealed a significant interobserver variability in the reporting of abnormal DMSA renal scans compared with the previously published studies [132], which should be kept in mind when making clinical decisions.

While DMSA scans correlate with acute pyelonephritis, they are not recommended in the standard management of acute pyelonephritis. Cortical defects identified on a DMSA scan performed during or shortly after APN may be due to preexisting lesions (either acquired RN or congenital RN) or to the acute inflammatory reaction associated with acute pyelonephritis. A delay in performing the DMSA scan to at least 4–6 months post-UTI allows the acute inflammatory reaction to subside, at which point any persistent cortical defects are assumed to represent permanent renal scarring [133].

Jodal et al. have suggested the use of the DMSA renal scan as an initial study in the evaluation after diagnosis UTI in children [134]. This “top down” approach is an alternative to a VCUG after UTI, also called the “bottom up” approach. However, the DMSA scan results in more radiation exposure than the VCUG or the nuclear cystogram. Due to a shortage of Technetium 99^{m} dimercaptosuccinic acid, many centers are using 99^{m}Tc-glucoheptonate as the tracer and this is less sensitive for the detection of renal scars.

Magnetic Resonance Imaging (MRI)

MRI allows discrimination between areas of swelling from scarring, both of which look similar on DMSA scintigraphy (see ▶ Chap. 6, “Imaging Kidneys and the Urinary Tract”). MRI also allows the diagnosis of other coexisting conditions such as nephrolithiasis, which is not diagnosed by DMSA scintigraphy. However, routine use of MRI is less practical because of limited availability, the need for prolonged sedation, and the high cost.

Biomarkers of Renal Injury

Severe VUR may interfere with tubular function including urine concentrating abilities. Urine levels of N-acetylglucosaminidase (NAG) and urine osmolality have been examined to determine if they predict severe VUR. NAG is an enzyme produced by lysosomes within proximal tubular cells. Garcia-Nieto et al. assessed one hundred and sixty-three children and found that urine osmolality was significantly decreased in children with severe VUR even without evidence of renal scars when compared to children without VUR and children with low grade VUR. They also found that urine NAG was significantly increased in those children with severe VUR (higher than grade 3) when compared to urine NAG levels in children with mild VUR and those without VUR [135]. Procalcitonin levels in the blood have also been used to predict VUR. Procalcitonin is the prohormone of calcitonin and is an early and sensitive marker of bacterial infection. In infants less than 2 years of age who presented with a febrile UTI, an elevated procalcitonin level $\geq$1.0 ng/mL predicted both acute pyelonephritis and VUR identified by voiding cystourethrogram [136].

Numerous noninvasive biomarkers have been investigated for their usefulness in early diagnosis and monitoring of the progression of renal scarring. These include proteinuria, renal tubular enzymes such as NAG [137], renal tubular brush-border antigens (BBA) [138], epidermal growth factor [139], cytokines such as interleukin (IL)-8 [140] and IL-6, soluble tumor necrosis factor (TNF) receptor-1 [141], endothelin-1 [142], and prostaglandin E2 [143]. Low molecular weight proteins, such as beta 2-microglobulin (B2M), retinol-binding protein (RBP), alfa 1-microglobin (A1M), and lysozyme, pass freely through the glomerular basement membrane and are almost completely reabsorbed by the proximal renal tubule [144]. Their urinary excretion increases in proximal tubular damage, including that due to reflux nephropathy [69, 145]. An increased serum level of beta 2 microglobulin has also been associated with reflux nephropathy [146].

Proteinuria is a well-known predictor of renal disease progression due to RN [147]. Proteinuria is severe when associated with FSGS. A significant correlation exists between albuminuria and GFR [69]. In contrast to overt proteinuria, persistent excretion of small amounts of albumin, also called microalbuminuria, is helpful in diagnosing glomerular damage at a very early stage, as demonstrated in patients with diabetes mellitus [148]. In patients with RN, microalbuminuria has been reported around the same time as the appearance of abnormal levels of low molecular weight proteins in the urine [69, 145], and its excretion increases with increasing severity of VUR and renal scarring [149]. In a study of children with bilateral VUR with renal scarring and normal creatinine clearance, microalbuminuria was detected in 53.5% of the cases [66]. The diagnosis and monitoring of microalbuminuria offers the potential therapeutic possibility of using an angiotensin converting enzyme inhibitor (ACEI) and/or an angiotensin receptor blocker (ARB) to slow the progression of renal damage [150, 151].

Medical Management of VUR

For many decades, the management of VUR has been driven by the belief that VUR predisposes to recurrent UTI and renal parenchymal damage. Various treatment strategies have been used with the ultimate objective of preventing renal injury. The two main treatment modalities that have been practiced are long-term antimicrobial prophylaxis and surgical correction. The third option that has come up recently is surveillance with no routine prophylaxis or surgical intervention.

Antimicrobial Prophylaxis

The effectiveness of antimicrobial prophylaxis in the prevention of UTI recurrence has been studied extensively (see ▶ Chap. 55, “Urinary Tract Infections in Children”). The RIVUR trial revealed that trimethoprim-sulfamethoxazole (TMP/SMZ) prophylaxis reduced the risk of UTI recurrence by 50%. Similar results were reported by another placebo-controlled-double-blind (PRIVENT study) trial [152]. Combined results from the RIVUR and Careful Urinary Tract Infection Evaluation (CUTIE) studies revealed that toilet-trained children with VUR and BBD exhibit the greatest benefit from antimicrobial prophylaxis [153]. However, many other randomized studies have shown either no [154–156, 157, 158] or a female-restricted beneficial effect with prophylaxis [159]. Systematic reviews and meta-analyses have also reported mixed results, some concluding that prophylaxis is effective [160, 161] while others reporting that prophylaxis offers none or very little advantage for the prevention of UTI recurrence

[162, 163]. These variations in results have been attributed to significant differences in study designs, including patient inclusion and exclusion criteria [164]. No study has demonstrated any beneficial effect of antimicrobial prophylaxis for the prevention of renal scarring. However, none of these studies were powered to evaluate renal scarring as the primary outcome.

The antimicrobial agents most appropriate for prophylaxis include trimethoprim-sulfamethoxazole, trimethoprim alone, nitrofurantoin, or cephalexin (see ▶ Chap. 55, "Urinary Tract Infections in Children"). In view of increasing resistance of *E. Coli*, ampicillin or amoxicillin are less effective as prophylactic agents [165–167] and are not generally prescribed beyond the first 2 months of life. During the first 2 months of life, it is advisable to avoid TMP-SMZ because it may worsen hyperbilirubinemia and promote neurotoxicity. In toilet trained children, antibiotic prophylactic medication is generally administered at bed time, though this recommendation is not evidence-based. The prophylactic dose of antimicrobials is one-fourth to one-half of the therapeutic dose for acute infection. The dosage for commonly used antimicrobials for UTI prophylaxis is shown in Table 3.

Antibiotic resistance is a major risk of long-term prophylaxis and hence the latter should be used selectively. In cases with febrile UTI and VUR, the American Urological Association (AUA) recommends continuous antibiotic prophylaxis in children under 1 year of age and a selective approach in older children based on patient age, severity of VUR, recurrence of UTI, presence of BBD, and renal cortical anomalies [168]. The European Association of Urology/European Society of Pediatric Urology, the Swedish and the Italian Society of Pediatric Nephrology also recommend a more selective approach based on a combination of patient age, severity of VUR, and the presence of renal scarring [169–171]. Other factors that should be considered before initiating long-term antimicrobial prophylaxis include status of toilet training, risk of antibiotic resistance, anticipated compliance with daily medication administration, parental choice, and the medication expense. In all recommendations, younger age is a particular consideration for prophylaxis because infants may present with nonspecific clinical signs with a UTI. In addition, infants have risks for other potential complications including difficulty in getting urine specimens, a higher likelihood of hospitalization for IV antibiotic administration and hydration, an increased risk of septicemia, and greater family disruption and parental anxiety. In some cases, "preemptive" antimicrobial prophylaxis may be necessary to lower the risk of first UTI such as in those with high-grade VUR diagnosed during workup for antenatal hydronephrosis.

Table 3 Antimicrobial agents for urinary tract infection prophylaxis [188]

Antimicrobial agent	Dose
Trimethoprim (TMP)–sulfamethoxazole	2 mg TMP/kg/day
Nitrofurantoin	1–2 mg/kg/dose
Cephalexin	10 mg/kg/dose
Amoxicillin	10 mg/kg/dose

Secondary analysis of the RIVUR study revealed that patients who took TMP/SMZ $<70\%$ of the time were 2.5 times more likely to have a recurrent UTI (95%CI 1.1–5.6) and were at highest risk for renal scarring ($OR = 24.2$, 95%CI 3.0–197) as compared to more adherent patients [172]. The RIVUR study also revealed that long-term prophylaxis with TMP/SMZ was not associated with an increased risk of skin and soft tissue infections, pharyngitis or sino-pulmonary infections [173], or excessive weight gain [174]. Another study reported no abnormalities in blood chemistries, renal function, or complete blood count results in children receiving long-term TMP/SMZ prophylaxis for a duration of 2 years [175]. Regarding the cost-effectiveness of antibiotic prophylaxis, one study revealed that prophylaxis was associated with marginally higher costs as compared to placebo [176], while another study reported that prophylaxis was more cost effective than observation in children with high grade (grade IV), but not low grade VUR. These findings should be considered in light of the fact that the large majority of children with VUR do not have high-grade disease [177].

The duration of prophylaxis depends on multiple factors. Treatment duration may range from a few days until a VCUG can be obtained in those with a recently diagnosed UTI to a few years for children with known VUR and UTI risks. Other factors that impact the duration include the age of the patient, the severity of the VUR, the frequency of UTI, BBD, and the degree of renal scarring, if present.

Bladder Bowel Dysfunction

The appropriate management of BBD is necessary to prevent recurrence of UTI, to promote resolution of VUR and to prevent further renal injury. Treatment of constipation by dietary measures, behavioral therapy, and laxatives helps to reduce UTI recurrence and to treat enuresis (see ▶ Chap. 59, "Enuresis") and uninhibited bladder contractions. Timed, frequent, and complete voiding every 2–3 h is a crucial part of management. Pelvic floor exercises, biofeedback, and/or anticholinergic medication or alpha-blockers may be required to improve bladder function. Anticholinergic medications may however worsen constipation. Conservative medical treatment coupled with computer game-assisted pelvic floor muscle retraining can decrease the incidence of breakthrough UTIs and facilitate VUR resolution in children with voiding dysfunction and VUR. Continuous intermittent catheterization may be necessary in extreme cases, as seen in Hinman's syndrome where there is functional bladder outlet obstruction from a nonneurogenic neurogenic bladder (see ▶ Chap. 58, "Bladder Disorders").

Hypertension and/or Proteinuria

Appropriate management of hypertension and/or proteinuria is important to slow down the progression of renal disease. While many antihypertensive drugs exist, angiotensin converting enzyme inhibitors (ACEI) or angiotensin II receptor blockers (ARB) are preferred due to their renoprotective effect. Studies have revealed that in addition to lowering blood pressure, ACEIs reduce proteinuria due to reflux nephropathy. In a study by Lama et al [150], 15.5% of children with VUR and reflux nephropathy had microalbuminuria. Treatment with an ACEI (captopril) for 2 years was associated with decreased microalbuminuria. Of note, GFR, serum creatinine, and BP remained stable. Notably, it is not known whether this antiproteinuric effect slows down the progressive loss of renal function. In patients with a unilateral poorly functioning scarred kidney, surgical removal of the affected kidney may normalize blood pressure.

Surgical Management of VUR

Surgical correction of VUR is usually reserved for patients with high-grade VUR, recurrent UTI despite antibiotic prophylaxis, noncompliance or intolerance to prophylactic antibiotics, and/or the worsening of renal scars [178]. Open ureteral reimplantation remains the mainstay of surgical correction for VUR, although endoscopic treatment is also widely used, particularly for low grade VUR. Laparoscopic reimplantation techniques (with or without robotic assistance) have increased in recent years but utilization remains limited to specific centers. Endoscopic treatment involves subureteral or intraureteral injection of a bulking agent (most commonly dextranomer/hyaluronic acid (Deflux®). The decision for timing and type of intervention is based on the age of the patient, the status of the kidneys, the grade of VUR, and parental/patient wishes.

Endoscopic Management

Endoscopic treatment is performed under anesthesia in an outpatient setting and involves the injection of a bulking agent in a subtrigonal location at the ureterovesical junction in the bladder (STING procedure). With the use of cystoscopy, the ureteral orifice is identified and an endoscopic needle is utilized to inject material under the ureteral orifice in the submucosal space.

Currently, endoscopic treatment of reflux with dextranomer hyaluronidase (Deflux®) is used by many as the first-line surgical treatment in children with low grades of VUR. Meta- analysis of all of the endoscopic modalities used for management of VUR indicates that rates of cure per ureter for grades I and II were 78.5%, grade III were 72%, grade IV were 63%, and grade V were 51%. Success rates of 68% were noted for those patients failing first injection and 34% for those failing a second injection. Reduced success rates were noted for those patients with duplicated systems and those with neurogenic bladders [179]. The success rates and the minimally invasive nature of endoscopic procedures have led to a substantial increase in the number of procedures being performed.

A systematic review revealed a success rate of 77% at 3 months after a single injection. Efficacy ranged from 81% for grade I VUR to 62% for grade V VUR [180]. Another study with 5 years of follow-up reported success rates of 68% [181]. Fortunately, no one has reported particle migration with the use of dextranomer/hyaluronic acid copolymer beads and the procedure is being used in complex urological conditions including ureteroceles, duplicated systems, and even failed open reimplants.

Rarely, postoperative ureteral obstruction has been noted in patients following injection therapy. A higher incidence of this complication has been noted in children with voiding dysfunction and a neurogenic bladder. Calcification of the implant of dextranomer/hyaluronic acid can resemble a distal ureteral calculus. Some patients have been misdiagnosed as having a possible obstructive distal ureteral stone when in fact they had an asymptomatic remnant of the bead that caused this appearance on ultrasound.

Laparoscopic Ureteral Reimplantation

Laparoscopic ureteral reimplantation has the benefit of providing results that are comparable to open surgery, with the promise of a minimally invasive approach. The procedure is typically performed using a transperitoneal approach and reimplantation is performed using an extravesical technique. Laparoscopic reimplantation has been associated with long operative times and high cost when disposable equipment is utilized. Additionally, appropriate patient selection is critical for surgical success using laparoscopy. Ureteral injury has been noted with this procedure and is related to the steep learning curve associated with complex laparoscopy. Additional complications that have been noted include ureteral leak in 12.5% and ureteral stricture in 6.3% [182]. Overall success with correction of VUR is similar to the open procedures [182]. This procedure has gained wider acceptance with the use of operative robots that permit greater ease of intracorporeal suturing.

Open Surgical Techniques

The gold standard for the surgical management of VUR remains the open approach. The most commonly performed open technique is the Cohen cross-trigonal reimplantation. This procedure has wide applicability and can be performed even in the presence of duplicated systems and other intravesical abnormalities. The success rate of this procedure for the correction of reflux is 98% [183]. Indeed, many clinicians have stopped performing follow-up VCUG studies to confirm the resolution of reflux after this procedure. Improvements in surgical anesthesia and postoperative pain management have allowed children to be managed with a 24- to 48-h hospitalization. Some children have even been managed as outpatients.

If residual VUR is noted following surgical reimplantation, continued monitoring of the patient and repeat VCUG testing 3–4 months later may show further resolution. Most children that have residual VUR following open surgery have a lower grade of VUR than their original grade. Contralateral VUR is noted in 19% of patients that have had unilateral ureteral reimplantation [184]. The majority resolve over the ensuing 2 years and are felt to be secondary to trigonal changes following ureteral reimplantation. Ureteral stricture has also been reported and is secondary to ischemia of the distal ureter. Endoscopic access to the ureter following ureteral reimplantation can be difficult and therefore later management of stones may be difficult.

Published Guidelines on UTI/VUR

Many guidelines have been published on the management of UTI and/or VUR. These include the Swedish [171], National Institute for Health and Clinical Excellence (NICE), United Kingdom

[185], American Academy of Pediatrics (AAP) [186], the recently updated American Association of Urology (AUA) [168], and the Italian Society of Pediatric Nephrology (ISPN) [187] guidelines (see ▶ Chap. 55, "Urinary Tract Infections in Children"). None of the recommendations advise a routine VCUG after the first febrile UTI. NICE and the AAP do not recommend routine antimicrobial prophylaxis, whereas the Swedish, ISPN, and the AUA recommend a selective use of antibiotic prophylaxis. None of these recommendations support the use of the DMSA renal scan in the acute management of febrile UTI.

Conclusion

The emerging knowledge about VUR has generated a lot of interest among clinicians as well as researchers. Clinical and possibly genetic differences have been noted between VUR diagnosed during sibling screening, during follow-up for antenatal hydronephrosis or after UTI. Additionally, the role played by bladder and bowel dysfunction and/or chronic constipation in the resolution of VUR and the frequency of UTI have not been completely elucidated. Prevention of renal scars in children with VUR and the preservation of renal function in those with renal scars remains the most important objective. The current management of VUR focuses on the prevention of UTI, with curative surgery limited primarily to children that fail conservative measures. Antimicrobial prophylaxis reduces the recurrence of UTI but its role in the prevention of renal scarring remains to be determined. A better understanding of gene mutations that lead to VUR and recurrent UTI and/or renal scarring is likely to help resolve some of the challenges faced in the management of VUR and prevent renal injury.

Abstract

Congenital obstructive uropathy, a major cause of chronic kidney disease, is defined as kidney, ureter, and/or bladder injury associated with obstruction of the urinary tract. Congenital obstructive uropathy arises from malformation of the renal collecting system, constituted by the calices, pelvis, and ureter, the bladder and urethra, and the connections between the ureter and pelvis and the ureter and bladder. Congenital obstructive uropathy is caused by a polymorphic group of unilateral or bilateral upper and lower urinary tract malformations. Presenting most commonly as antenatal hydronephrosis, these disorders range in severity from self-resolving pelviectasis and/or hydroureter to a fixed physical obstruction of the ureteropelvic junction, ureterovesical junction, or urethra causing kidney injury. In this chapter, the clinical assessment of urinary tract obstruction and the pathobiology of obstructive uropathy-associated kidney injury are described from observations in animal models and descriptive analyses of human kidney tissue. Genes and genetic pathways that control the embryonic development of the ureter and its connections with the bladder are highlighted as well genetic mutations associated with malformation of the ureter, ureteropelvic junction, ureterovesical junction, and urethra. A clinical classification of antenatal urinary tract dilatation is presented; for each specific disorder, genetic etiologies, diagnosis, use of static and dynamic imaging modalities, natural history, and treatment approaches are described.

Obstructive uropathy

Introduction

Congenital obstructive uropathy is a heterogeneous group of pathologies with a varying natural history. Obstruction of the urinary tract can be at the level of the ureteropelvic junction, the ureterovesical junction, the bladder outlet, or urethra. It can be either unilateral or bilateral and it may involve some or all of the urinary tract. Congenital obstructive uropathy represents a major cause of renal failure in infants and children. Together with renal hypoplasia and dysplasia, it accounts for almost half of all cases of chronic kidney diseases in children.

Epidemiology

Urinary tract abnormalities identified by ultrasound are one of the most common anomalies with a rate of 1:250 to 1:1000 pregnancies [1]. Congenital obstructive uropathies account for most of these cases: approximately 1:2000 pregnancies. The mean prevalence of all types of renal malformation is 1.6 per 1000 births. The most frequent diagnosis is hydronephrosis with more than 80% being detected prenatally [2, 3]. Unilateral hydronephrosis is more common than bilateral, and most cases are mild and will resolve spontaneously. The differential diagnosis of hydronephrosis includes ureteropelvic junction obstruction, vesicoureteral reflux, ureterovesical junction obstruction, posterior urethral valves, prune belly syndrome, urethral atresia, and duplicated collecting system with ureterocele. Ureteropelvic junction obstruction is the most frequent cause of hydronephrosis (reported incidences of 39–64%), followed by vesicoureteral reflux (33%) and ureterovesical junction obstruction (9–14%). The incidence of lower urinary tract obstruction is 2.2 per 10,000 newborns with posterior urethral valves being the most common malformation at 64% (1.4:10,000 births), followed by urethral atresia at 39% (0.7:10,000 births) and Prune belly syndrome (Eagle-Barratt syndrome) (4%) [4].

Definition of Obstruction

Whitaker et al. described urinary tract obstruction as any condition “that impairs urinary drainage from the pelvicalyceal system and leads to increased pressure and reduced urine flow rate” [5]. This was the first approach to define obstructive uropathy from a functional perspective. Koff et al. added potentially endangered renal function to impaired urinary drainage in the definition of obstruction, resulting in “any restriction to urine flow that will cause progressive renal deterioration” [6]. Peters et al. created the most recent and generally accepted definition describing obstruction as “any condition that, left untreated, endangers renal function and growth potential” [7]. Clinically, obstruction is usually presumed when urinary tract dilatation (i.e., hydronephrosis) is detected by ultrasound. But not every patient with hydronephrosis has an obstruction (or significant obstruction) as most cases of antenatal hydronephrosis will improve without surgical intervention or renal damage. It is important to state that hydronephrosis *per se* does not correlate with the affected kidney’s function. Hydronephrosis is problematic when it endangers renal function. At the time of diagnosis, some patients will have irreversible renal damage, whereas others will have progressive renal injury if left untreated. It is still a challenge for physicians to identify and categorize this heterogeneous group of obstructive pathologies.

Pathophysiology

The urinary tract consists of conduits and reservoirs transporting the urine produced by the kidneys. To better understand the pathophysiology of obstructive uropathy, the properties of this system have to be considered, including structural compliance, flow impairment, renal function, and urine production. It is important to understand that the onset and the duration of obstruction correlate with abnormal kidney development and loss of kidney function. In fetal development, urinary tract obstruction impairs renal growth and development. It is therefore fundamentally distinct from obstruction acquired later in life. The development of congenital obstructive uropathy is regulated by a complex interplay of genetic and nongenetic factors, only some of which have been identified [8–12].

Animal Models

Congenital obstructive uropathy initiates a complex sequence of events resulting in impaired renal function. Its pathophysiology has been studied intensively, leading to the development of multiple animal models, including complete and partial ureteral obstruction, unilateral and bilateral obstruction, and acute and chronic obstruction [8, 9]. Experimental obstructive uropathy is usually created by unilateral ligation of the ureter. Advantages of this surgical model include experimental manipulation of the severity, duration and timing of obstruction, as well as the study of recovery following release. The unilateral ligation of the ureter induces progressive tubular cell injury in the kidney, including apoptosis, necrosis, and necroptosis [13], reduced proliferation, loss of differentiation, and tubular atrophy. Ureteral obstruction also leads to interstitial inflammation, interstitial fibrosis, and extracellular matrix deposition. Experimental obstructive uropathy induces glomerular and vascular hemodynamic changes that are different in neonatal mice and rats when compared to adult rodents in which nephrogenesis is complete.

Tubular Injury After Ureteral Obstruction

Early changes observed after ureteral obstruction consist of tubular dilatation, which is mostly pronounced in the collecting ducts. The mechanical stretch of tubular cells induces progressive tubular apoptosis accounting for significant loss of renal tissue. A variety of molecules mediate these tubular changes, including those related to apoptosis and cell cycle regulation (caspases, intrinsic and extrinsic death pathway molecules, reactive oxygen species, catalase, and inhibitors of cyclin-dependent kinases p27 and p21) [9]. Upon injury, some tubular segments lose epithelial markers (E-cadherin) and gain de novo-expression of mesenchymal cell markers (α-smooth muscle actin, vimentin), suggesting transformation/dedifferentiation of tubular epithelial cells into mesenchymal cells or epithelial-mesenchymal transformation [14, 15]. Ureteral obstruction also leads to glomerulotubular disconnection, resulting in atubular glomeruli and aglomerular nephron segments [16]. The functional tubular changes observed after ureteral obstruction include impaired reabsorption of solutes and water, and reduced capacity to concentrate and acidify the urine [17].

Interstitial Inflammation After Ureteral Obstruction

Unilateral ureteral obstruction induces recruitment and infiltration of inflammatory cells into the kidney. This inflammatory infiltrate consists predominantly of macrophages and activated T-lymphocytes, which together with injured tubular cells release chemokines, proinflammatory and profibrotic cytokines, and reactive oxygen species. Neutrophils are rarely found in obstructed kidneys. In addition to producing cytokines, infiltrating leukocytes also release chemokines (e.g., CCL2) and express chemokine receptors (e.g., CCR1, CCR5) as well as other receptors (Toll like receptor-2), activating both paracrine and autocrine loops for macrophage and T-cell recruitment. Multiple chemokines, chemoattractants, and adhesion molecules regulate the interstitial inflammation (CCL2, osteopontin, IL-1, VCAM-1, ICAM-1, angiotensin II, selectins, β2-integrins, and receptor for advanced glycation end products – RAGE) [18]. Different macrophage subpopulations, some harmful and others protective, have been found in the kidney after unilateral ureteral ligation and may be important targets for future therapies [19].

Interstitial Fibrosis After Ureteral Obstruction

Experimental ureteral obstruction eventually leads to interstitial fibrosis, characterized by the activation of interstitial fibroblasts, the production and deposition of extracellular matrix and the loss of peritubular capillaries in the obstructed kidney. Increased fibroblast density in the kidney was traditionally explained by the local proliferation of resident fibroblasts. Recently, it has been shown that this mitogenic process accounts for only about half of interstitial fibroblasts. Other mechanisms such as recruitment of bone marrow-derived fibrocytes from the circulation and epithelial to mesenchymal transformation of tubular cells may contribute to the increased number of interstitial renal fibroblasts [14, 15, 20]. Pericytes and endothelial cells have been identified as additional sources of interstitial fibroblasts [21]. Various molecules drive these interstitial changes like the regulators of epithelial to mesenchymal transformation (hepatocyte growth factor, bone morphogenic protein 7, TGF-β1, nestin, and HIF1-α) [22], hypoxic injury responses, cytokines, and growth factors (TGF-β1, EGF, VEGF, IGF-1, PDGF-C, connective tissue growth factor and TNF-α) [9]. These changes collectively induce progressive scarring, and the loss of renal tissue and kidney function. Extracellular matrix proteins contributing to fibrosis in the obstructed kidney include collagen types I, II, III, IV, V, VII, and XV; fibronectin, laminin, and heparin sulfate proteoglycans.

Glomerular, Vascular and Hemodynamic Changes After Ureteral Obstruction

In adult animals with ureteral obstruction, glomerular and vascular changes are observed in advanced stages. Nonspecific glomerular changes including capillary wall thickening or collapse, global sclerosis, and vascular intimal thickening reflect chronic ischemia of the obstructed kidney. In contrast to the adults with obstruction, glomerular changes are much more pronounced and occur earlier in neonatal animals [23]. Renal blood flow, glomerular filtration rate, and tubular function change immediately after ureteral obstruction. After a brief period of hyperemia and transient increase in renal blood flow, a progressive and permanent vasoconstriction leads to a decline of renal perfusion and glomerular filtration rate. Vasoconstrictive agents like angiotensin II, thromboxane A2, and prostacyclins in combination with a reduced production of vasodilating substances including nitric oxide, prostaglandins, and platelet-activating factor regulate these functional changes [9].

Renal Injury in Neonatal Ureteral Obstruction

Most preclinical studies to investigate the pathophysiology of ureteral obstruction have been performed in adult animals. Few studies have been conducted in fetal sheep and monkeys or in neonatal rodents (mice and rats). In humans, nephrogenesis is complete at 34–36 weeks of gestation [24] and thereafter only functional maturation occurs. In contrast, in rats and mice only 10% of mature glomeruli are generated at birth, with the remaining nephrons formed postnatally. Based on the duration of nephrogenesis, the neonatal rat or mouse parallels the mid-trimester human fetus [9]. This is the time when renal obstruction usually starts in the human system. Thus, ureteral obstruction experimentally conducted in the newborn mouse offers a suitable animal model to investigate obstructive uropathy.

Moreover, pioneering work by Chevalier and his coworkers established a model of neonatal obstructive nephropathy in newborn mice and rats at the second day of life. Their technique of unilateral ureteral obstruction allows for the study of urinary blockage during kidney development [25]. Complete unilateral ureteral obstruction in neonatal rodents results in arrested renal development, renal dysplasia, fewer glomeruli, and reduced glomerular surface area; it impairs growth and maturation, and ultimately reduces the number of nephrons [23]. The severity of renal injury depends on the degree and the duration of obstruction. Neonatal ureteral obstruction for four days (and release thereafter) reduces renal growth by 60% and the number of glomeruli by 50% [26]. Neonatal ureteral ligation leads to hemodynamic changes, tubular atrophy, interstitial fibrosis, and abnormal development of the renal vasculature. Similar histologic lesions were found in kidney biopsies of children obtained during pyeloplasty [27]. Some of the underlying pathways driving interstitial inflammation, tubular apoptosis, and interstitial fibrosis in neonatal ureteral obstruction have been identified (Table 1, modified from [28]).

For lower urinary tract obstruction, the fetal sheep has been the most used model, with the majority of work done by Harrison and colleagues. Using this model, the effect of ureteric and urethral

Table 1 Pathways for obstructive renal injury

Apoptosis	Inflammation	Fibrosis
Hypoxia, Ischemia	Angiotensin II	TGF-β
Reactive oxygen species	TGF-β	Angiotensin II
Caspases	Chemokines (CCL2, CCL5)	EMT / EndMT
Cellular stretch	Adhesion molecules (Selectins, β2-Integrins), RAGE	Activated Myofibroblasts
EGF	Macrophage infiltration	ECM, α-SMA
TNF-α	NF-κB	SMAD2, SMAD3

Legend: Pathogenesis of obstructive uropathies. There are three major pathways for obstructive renal injury: apoptosis (and other forms of cell death), interstitial inflammation, and eventual interstitial fibrosis. Epidermal growth factor (EGF), Tumor necrosis factor-α (TNF-α), Transforming growth factor-β (TGF-β), Receptor for advanced glycation end products (RAGE), Nuclear factor-κB, (NF-κB), Epithelial-mesenchymal transition (EMT), endothelial-mesenchymal transition (EndMT), Extracellular matrix (ECM), and α-smooth muscle actin (α-SMA). Table modified from [28] obstruction, both partial and complete, and its effects on pulmonary and renal development has been identified [29]. Complete urethral obstruction produced severe hydronephrosis, megaureter, megacystis, and pulmonary hypoplasia, but not cystic and/or dysplastic changes in the kidney. In contrast, complete unilateral ureteral obstruction in the fetal lamb induced dysplastic kidneys. These histologic lesions were similar to those seen in the human fetus [30]. In addition, in-utero decompression either prevented or greatly improved renal dysplasia [31]. Other animal models have reproduced the finding of dysplastic kidneys with ureteral obstruction [31].

Unfortunately, interstitial fibrosis and irreversible renal damage, which are present in patients with poor kidney function, rarely improve after surgical correction. Therefore, the focus of most studies has more recently shifted to the identification of novel biomarkers to characterize and identify obstructive uropathies before permanent damage has occurred [32].

Genetics

Experimental studies to identify genetic defects in patients with obstructive uropathy have provided an enormous wealth of data. The mouse has been instrumental in further characterizing putative genes involved in obstructive uropathy. The strong similarities between the human and the mouse genome together with genetic engineering technologies provided excellent research tools to study the effects of human mutations *in vivo* [32, 33]. Although only a few causative genes associated with obstructive uropathy in humans have been discovered so far, basic research in this area gave important insights on early urinary tract development (Table 2). Most cases of kidney and urinary tract anomalies are sporadic and restricted to the urinary tract [24]. The majority of sporadic cases cannot yet be explained by monogenic causes. Only some subsets of "congenital anomalies of the kidney and urinary tract" (CAKUT) are part of a syndrome or are associated with a positive family history [1, 24]. To date, 40 genes have been identified as monogenic causes of isolated CAKUT and approximately 150 genes have been identified for syndromic CAKUT [34–36].

Genes and Signaling Pathways in Human and Mice

Many genes and signaling pathways have been identified to play important roles in early ureteric budding and ureter development [37]. These include the renin-angiotensin system (e.g., *Agt, Ren, Agtr1, Agtr2*), the receptor tyrosine kinase (RTK) signaling pathway (e.g., *Gdnf, Ret, Fgfr2*), the Wnt signaling pathway (e.g., *Ctnnb1, Wnt7b, Wnt9b, Fzd1*), the Hedgehog signaling pathway (e.g., *Shh, Gli3, Smo, Tshz3*), the TGF-β signaling pathway (e.g., *Bmp4, Smad4*), and the retinoic acid-mediated nuclear receptor signaling pathway (e.g., *Rara, Rarb*). Urinary tract diseases can modify the expression and activity of these genes and pathways [38].

Genetic studies in both human and mice have identified many genes associated with hydronephrosis due to urinary tract abnormalities [36, 39] (also see ▶ Chap. 1, "Pre-natal Development of the Kidneys and Urinary Tract"). Antenatal hydronephrosis can originate from kidney defects (e.g., mutations in *AQP2* that encodes the aquaporin 2 water channel in the collecting tubule) [40], or from defects in the ureter such as vesicoureteral reflux or from urinary tract obstruction [41, 42]. Mutations in many genes controlling the developmental process of the ureter have been shown to cause hydronephrosis in mice [39]. In addition, mutations in several murine genes have been shown to cause ureteropelvic junction obstruction and ureter-bladder connections defects [43–45]. Loss of both retinoic acid receptor alpha (*Rara*) and beta (*Rarb*) in mice lead to megaureter and hydronephrosis due to abnormal apoptosis mediated by vitamin A signaling at the ureter-bladder insertion site [43]. Deletions of uroplakins (*Upk3a* and *Upk2*) in the urothelium in mice cause loss of the superficial cell layer, overgrowth of the urothelium, urothelial leakage, and vesicoureteral reflux [46]. Stromal cells are also important for ureteral development and function [47]. Loss of Disc-large homolog 1 (*Dlg1*) causes absence of the stromal cell layer in the ureter, which leads to abnormal ureteral smooth muscle cell orientation, impaired ureteral peristalsis, and severe antenatal hydronephrosis [47]. *Dlg1* is the only gene identified so far that is required for ureteral stromal cell formation. Many genes associated with hydronephrosis in mice are genes controlling ureteral typical smooth muscle cell development [48]. These include genes in the sonic hedgehog pathway (e.g., *Shh, Gli3, Smo, Tshz3*) [49, 50], the TGF-β pathway (e.g., *Bmp4, Smad4*) [51, 52], and the Wnt pathway (e.g., *Ctnnb1*) [53]. In mice, loss of the T-box transcription factor *Tbx18* induces failure of the ureteral mesenchymal cells to differentiate into ureteral smooth muscle cells as well as an abnormal differentiation of the urothelium, leading to ureterovesical junction obstruction, short hydroureter, and antenatal hydronephrosis [54]. The abnormal smooth muscle phenotype in *Tbx18* mutant mice may be caused by the downregulation of the sonic hedgehog signaling (e.g., *Ptch1*) in the ureteral mesenchyme and lower *Bmp4* expression in the ureter [54]. These results underline the importance of typical smooth muscle cells in the ureter, which produce contractile forces to transport urine from the kidney to the bladder [55]. Different genes control the development of ureteral pacemaker cells and the peristalsis machinery [48, 50, 56, 57]. *Hcn3* (hyperpolarization-activated cation channel 3) plays a fundamental role coordinating proximal-to-distal ureter peristalsis [57]. Inactivation of *Smo* (Smoothened) and upregulation of the GLI3 repressor, two members of the sonic hedgehog signaling pathway, lead to abnormal ureteral peristalsis, nonobstructive hydronephrosis, and hydroureter in mice [50]. Although the urothelium and smooth muscle cells develop normally in these mutant mice, the number of ureteral pacemaker cells is significantly reduced. Mice with defective pacemaker cell differentiation show abnormal ureteral peristalsis and hydronephrosis [50, 58]. Consistent with these findings, mutations in *Gli3* gene have been identified in patients with the Pallister-Hall syndrome, which includes urinary tract phenotypes like hydronephrosis and hydroureter (Table 2) [59]. In the murine urinary tract, mesenchymal expression of one of the calcineurin subunit B isoform genes called *Cnb1* (also named *Ppp3r1*) is required for the development of the pyeloureteral peristalsis [56]. Tissue-specific knockout of *Cnb1* in mice causes an abnormal formation of the renal pelvis and ureter as well as defective peristaltic waves, which lead to progressive renal tract obstruction and hydronephrosis after birth [56].

The angiotensin type 1 receptor (*Agtr1*) plays an important role in ureteral peristalsis. *Agtr1* knockout mice have an abnormal renal pelvis and lack ureteral peristaltic waves, and subsequently develop a hydronephrosis phenotype [60]. However, no causative mutations in either *CNB1* or *AGTR1* have been reported in patients with urinary tract anomalies although mutations in *AGTR1* are associated with autosomal recessive renal tubular dysgenesis (RTD) [61]. Molecular mechanisms leading to hydronephrosis and hydroureter in the absence of

Table 2 Genes associated with hydronephrosis and/or hydroureter (no VUR) in human

Gene	Chr	Type of protein	Signaling	Human disease (OMIM)
AGTR2	Xq22-q23	G-protein coupled angiotensin II receptor	RAS	X-linked mental retardation-88 (OMIM 300852)
WFS1	4p16.1	Transmembrane protein		Wolfram syndrome (OMIM 222300): hydronephrosis, dilated ureters, distended bladder without VUR
FOXC1 FOXF1	6p25	Forkhead transcription factor	Foxc	Axenfeld-Rieger syndrome type 3 (OMIM 602482): UPJO
GLI3	7p13	Zinc finger	Hedgehog	Pallister-Hall syndrome (OMIM 146510)
RET	10q11.21	Receptor	RTK	Hydronephrosis, megaureters, renal dysplasia
STRA6	15q24.1	A receptor for retinol/retinol-binding protein complexes	Retinoic acid signaling	Hydronephrosis

Abbreviations: Chr: chromosomal location; Signaling: signaling pathway; RAS: Renin-angiotensin system. Table modified from [39] anatomic obstruction include T-box transcription factor 18 (Tbx18) or SIX-1-dependent delay in differentiation of ureteral smooth muscle cells [54, 62]. The Rearranged in Transfection (RET) tyrosine kinase signaling system is the major pathway guiding the normal development of the kidneys, ureters, peripheral, and enteric nervous system. In the kidneys, RET is activated by interaction with the ligand glial cell line-derived neurotrophic factor (GDNF) and its coreceptor GFRα1. This activated complex regulates a number of downstream signaling cascades that control proliferation, migration, and apoptosis. RET mutations are found in 5–30% of CAKUT patients [63], and a number of *Ret* mouse mutants show a spectrum of kidney and urinary tract defects reminiscent of CAKUT in humans [64]. Both, loss and overexpression of RET can cause urinary tract anomalies. Recently, it has been shown that in mice with a mutation in the RET-PLCγ docking site (Y1015), the common nephric ducts (CNDs) do not undergo timely degeneration and fail to separate from the Wolffian duct (WD), resulting in obstructive uropathy [65]. The ureter defect in RETY1015F mice is different from that in RET-null mice, as it manifests during the ureter maturation stage after the Wolffian duct has reached the cloaca. A phenotype similar to Y1015F ureter defects (ureterovesical junction obstruction) was shown in mice deficient for leukocyte antigen-related (LAR) family protein tyrosine phosphatase, receptor type S and F (PTPRS and PTPRF) [45]. These ureter-bladder connection defects cause urinary obstruction, hydroureter, and hydronephrosis in *Ptprs Ptprf* double deficient embryos [45]. Increased activation of RET-docking tyrosines in these mice implies an interaction between LAR and RET signaling pathways. Sprouty protein (SPRY1) inhibits RET tyrosine signaling by suppressing RAS-MAPK activity. Therefore, a *Spry1*-null mutation causes hyperactivation of the RAS-MAPK cascade. *Spry1*-null mice show multiplexed dysplastic kidneys with megaureters and an increased number of ureteric buds. Double knockout mice lacking RET-PI3K-MAPK signaling and *Spry1* show morphological correction of the renal anomalies in contrast to the individual null mice [66]. The mechanism for normalization of the renal defects was explained by an increase in RAS-MAPK signaling via a pathway other than RET. A possible candidate for this was FGFR signaling as in the absence of GDNF/RET signaling FGF7 can induce ureteric buds. Support for alternative tyrosine kinase activity came from compound homozygous mice lacking *Gdnf* or *Ret*, and *Spry1*. Deleting *Fgf10* from *Ret-Spry1* double nulls resulted in no ureteric buds, suggesting that FGF10 was the alternative RTK signal for ureteric bud induction [67].

Kidney and urinary tract development is sensitive to precise timing and to the level of MAPK activity. This activity can be altered by the dosage of the RET signaling complex, or through activation of key docking tyrosine of RET, or by interactions with negative regulators such as SPRY1 [64]. The GATA-RALDH2-RET molecular network plays a fundamental role in guiding the correct insertion of the nephric duct into the mouse bladder [44]. Absence of *Ret*, *Gata3*, or *Raldh2* causes similar defects of ureter insertion with urinary tract obstruction and hydronephrosis in mice [44].

Gene expression may also be regulated at the posttranscriptional level by noncoding microRNAs (miRNAs). A critical role for miRNAs in kidney development is evident from the observation that targeted genetic inactivation of Dicer, the miRNA-processing enzyme, in ureteric bud in mice results in hydronephrosis [68].

The broad phenotypic spectrum of obstructive uropathy and the variability in genotype–phenotype correlation indicate that its pathogenesis is a complex process depending on many factors. Derangements in cellular, molecular, and morphogenetic mechanisms that direct normal renal system development are important causes of congenital genitourinary disorders.

Genetics and the Renin-Angiotensin System

The renin-angiotensin system (RAS) plays a major role in controlling blood pressure, fluid, and electrolyte homeostasis. The developing mammalian kidney expresses all components of the RAS as early as the 5th week of gestation, when metanephric organogenesis is initiated [69]. Mutations in the genes encoding components of the RAS in mice cause diverse forms of congenital kidney and urinary tract malformations (CAKUT), which include hydronephrosis, hypoplastic medulla and papilla, thickening of renal arterial walls, duplex ureters, and vesicoureteral reflux [70]. The mechanistic basis of CAKUT due to RAS mutations involves hypoplastic ureteral smooth-muscle layer with impaired ureteral peristalsis [60]. Association of a single polymorphism in the human AT_2R gene (1332A>G transition) with CAKUT have been reported in several, but not all, studies. This alteration in the AT_2R is described in American and German Caucasian males with ureteropelvic junction obstruction, megaureter, and multicystic dysplastic kidneys [71]. The same polymorphism was detected in Korean children with unilateral multicystic dysplastic kidney, renal agenesis, and hydronephrosis [72], in Italian children with vesicoureteral reflux, hypoplastic kidneys, ureteropelvic junction obstruction, nonobstructive megaureter, and posterior urethral valves [73], and in Serbian children with ureteropelvic junction obstruction, vesicoureteral reflux, or megaureter [74]. In contrast, a large European study published by Cordell et al. found no association of primary vesicoureteral reflux with mutations in AT_2R [75]. This difference may be explained by limitations in study design, low penetrance of the mutation, or contribution of modifier genes. ACE polymorphism is also associated with kidney hypodysplasia caused by posterior urethral valves [76]. Collectively, these observations indicate that the pathogenesis of obstructive uropathy is a complex process that depends on the interplay of many factors. A concerted effort to provide new insights into pathologic processes is in progress within the Genitourinary Development Molecular Atlas Project (GUDMAP). Genetic counseling is recommended for all patients with familial cases of urinary tract malformations or newly diagnosed forms of CAKUT that suggest presence of genetic anomalies.

Classification

Table 3 shows the differential diagnosis of prenatally detected urinary tract dilatation. Idiopathic antenatal hydronephrosis (IAHN), defined as antenatal hydronephrosis not associated with other morphologic renal tract abnormalities, is the most common hydronephrosis phenotype detected by antenatal ultrasound [77]. Less common causes of hydronephrosis and, generally with greater pathologic significance, include ureteropelvic junction obstruction, ureterovesical junction obstruction, ectopic ureteral insertion with and without duplex system, posterior urethral valves, Eagle-Barratt syndrome, urethral atresia, and duplicated collecting system with and without ureterocele. Many of these prenatal dilatations will improve without surgical intervention or evidence of impaired kidney function. Nonobstructive causes of urinary tract dilation like vesicoureteral reflux must also be considered. The causes of obstruction can be classified on the anatomical level of obstruction (renal, ureter, bladder, or urethra) or on the underlying pathology (neoplastic, traumatic, inflammatory). Obstructive uropathies can be clinically classified as symptomatic or asymptomatic. Infants and children may present with febrile urinary tract infection, hematuria, a palpable flank mass, vomiting, or unexplained abdominal pain. However, with the use of antenatal ultrasound, symptomatic presentation has become less frequent. Occasionally, patients may show multiple abnormalities, for example, ureteropelvic junction obstruction and vesicoureteral reflux, which can be

Table 3 Causes of antenatally detected urinary tract dilatation

Causes of antenatally detected urinary tract dilatation
Idiopathic antenatal hydronephrosis
Ureteropelvic junction obstruction
Ureterovesical junction obstruction
Posterior and anterior urethral valves
Ectopic ureteral insertion w/o duplex system
Ureteral stricture
Retrocaval and retroiliac ureter
Ureterocele w/o duplex system
Vesicoureteral reflux
Prune belly syndrome
Extrinsic compression of the urinary tract
Neurogenic dysfunction, Megacystis microcolon intestinal hypoperistalsis syndrome
Complex anatomical abnormalities (cloaca, cloacal exstrophy)

difficult to discern. It is important to identify patients with involvement of both kidneys (bilateral ureteropelvic junction obstruction or ureterovesical junction obstruction), patients with a solitary kidney, or with poor function in the contralateral nonobstructed kidney. These children do not have the advantage of reserve functional kidney tissue and often benefit from surgical intervention. Poor excretion on nuclear scan could result from either poor kidney function or obstruction and as such can be difficult to identify those kidneys with obstruction. Under these circumstances, serial ultrasound examinations or magnetic resonance imaging (MRI) may be the best available indicator for surgical intervention.

Diagnosis

In the clinical setting, obstructive uropathy is assumed when dilatation, defined as an increased diameter of one or more components of the renal collecting system, is detected. Unfortunately, this dilatation does not necessarily correlate with the presence or degree of urinary flow impairment. Nonobstructive conditions can show similar findings (e.g., vesicoureteral reflux), and hydronephrosis *per se* does not correlate with kidney function. It is important to state that urinary tract dilatation also depends on the level of hydration. The fetal kidneys produce four to six times more urine before delivery than after; this increased volume may cause dilatation of the renal pelvis, at least transiently in early postnatal life [78]. All imaging techniques (ultrasound, nuclear scan, magnetic resonance urography) pre- and postnatally require sufficient hydration to depict and categorize urinary tract obstruction.

Prenatal Diagnosis

The majority of congenital abnormalities of the urinary tract are diagnosed during the second trimester ultrasound scan, which is usually performed at 18–20 weeks of gestation. However, with the increasing use of first trimester ultrasound screening, more severe renal abnormalities are being noted between 11 and 14 weeks [79]. The findings of prenatal ultrasound depend on the level and severity of the obstruction (Table 4). Unfortunately, no prenatal diagnostic test is available, which differentiates between obstructive and nonobstructive causes of hydronephrosis. Ultrasonography can detect increased echogenicity and cysts in the fetal kidney, which are suggestive of renal dysplasia; it can determine amniotic fluid volume, associated anomalies, and fetal sex. Predictors of outcome in lower urinary tract obstruction that can be identified by ultrasound include the gestational age at diagnosis, oligohydramnios, and kidney appearance. Detection of lower urinary tract obstruction (e.g., posterior urethral valves) before or at 24 weeks of gestation, oligohydramnios, and evidence of renal cortical cysts has been shown to predict poor outcome. Ultrasonography directs diagnostic procedures (amniocentesis) and therapeutic interventions (vesicoamniotic shunts). When ultrasound has proved unsatisfactory (e.g., in cases of maternal obesity or anhydramnios), magnetic resonance imaging is superior to provide sufficient anatomical detail.

Table 4 Society of fetal urology grading system of antenatal hydronephrosis

Grade	Renal pelvic complex	Renal parenchymal thickness
0	Intact	Normal
I	Mild splitting	Normal
II	Moderate splitting (confined to renal border)	Normal
III	Marked splitting (outside renal border, calyceal dilatation)	Normal
IV	Pelvicalyceal dilatation	Thin

Whereas fetal upper urinary tract obstruction, particularly unilateral, portends a more favorable prognosis, fetal lower urinary tract obstruction often has a less favorable outcome, due to associated cystic renal dysplasia, oligohydramnios, pulmonary hypoplasia, dysmorphia, and limb contractures. Prenatal diagnosis allows for the planning of appropriate prenatal and postnatal care, consideration of prenatal intervention, and psychological adjustment of the parents. For some fetal abnormalities of the lower urinary tract, uncertainty exists regarding best management [80]. The use of fetal urine samples, fetal serum, amniotic fluid, and/or fetal renal biopsies is still not widely used clinically. Also, the prognostic value of markers to assess fetal renal function is uncertain (with few exceptions) and the effectiveness of therapy remains to be established [80, 81]. The main goal of performing imaging studies early is to distinguish those kidneys that do not require surgery from those that will deteriorate and lose function or growth potential and thus benefit from surgery.

Fetal Urine Analysis

In the presence of severe fetal obstructive uropathy (e.g., posterior urethral valves) the analysis of fetal urine is most commonly used before performing *in utero* therapy. The first urine sample may not reflect kidney function, as this urine may have been in the bladder for some time. Sequential sampling of fetal urine seems to improve the accuracy. Often, values that remain stable or even increase over time are suggestive of renal dysplasia. Electrolytes (sodium, calcium, and chloride), α_1-microglobulin, β_2-microglobulin, total protein, microalbumin, N-acetyl-β-glucosaminidase, osmolality, and other urinary analytes (IGF-1, IGF-BP3, creatinine, and cystatin C) have been used as biomarkers for fetal kidney function. Recently, fetal urinary peptides have been shown to predict postnatal renal function in fetuses with posterior urethral valves [81]. Among more than 4000 fetal urinary peptides, 26 peptides were associated with end-stage kidney disease before the age of 2 years [81]. Fetal tubular dysfunction is suggested by increased urinary sodium concentrations. At 20–30 weeks of gestation, sodium concentrations in the fetal urine normally fall below 90 mmol/l. Fetal urinary sodium or chloride concentrations above 100 mmol/l have been shown to be predictive of fetal or perinatal death from renal and/or pulmonary failure [82]. Values of fetal urinary β_2-microglobulin > 13 mg/l, which is normally filtered by the glomerulus and $> 99.9\%$ reabsorbed in the proximal tubule, are associated with perinatal demise. The two tests most widely used to determine the need for *in utero* surgery were urinary calcium and sodium concentrations >95th percentile for gestation; however, a recent systematic review to evaluate the usefulness of fetal urine analysis in congenital urinary tract obstruction concluded that the evidence to support its use is insufficient [83].

Postnatal Diagnosis

In upper urinary tract obstruction (e.g., ureteropelvic junction obstruction) patients who elude antenatal diagnosis, may develop abdominal pain or discomfort, hematuria, and/or urinary tract infections. Recurrent episodes of vomiting may not be recognized to be related to obstructive uropathy. Patients with congenital anomalies (VATER/VACTER-L association, congenital heart disease, and CNS malformations) may be found to have urinary tract obstruction during the workup for their defects.

In patients with lower urinary tract obstruction, the presence of abdominal masses (bladder, kidney), delayed voiding (e.g., urethral valves), deficient abdominal wall musculature, or undescended testes (e.g., Eagle-Barratt syndrome) indicate the need for further evaluation. Unfortunately, a normal voiding pattern does not exclude urinary tract obstruction. In infants with a palpable bladder and in female newborns with interlabial cystic masses (prolapsed ureterocele) bladder outlet obstruction should be considered. Delayed diagnosis of lower urinary tract obstruction in children may lead to chronic kidney disease, hypertension, recurrent urinary tract infections, sepsis, growth failure, and urinary incontinence.

Imaging and Nuclear Medicine Studies

The evaluation of congenital obstructive uropathy includes the assessment of morphologic and structural changes (e.g., dilatation of the urinary tract, bladder wall thickness, kidney parenchyma) as well as the assessment of functional changes (e.g., impaired ^{99m}Tc-MAG-3 excretion or differential renal uptake). A combination of repeated imaging and nuclear scan examinations provides complementary information and helps to establish the diagnosis (see chapter “Diagnostic Imaging”).

Ultrasonography

Ultrasonography is the first noninvasive diagnostic test in urinary tract obstruction pre- and postnatally. It is widely available, relatively inexpensive, and allows for the morphological assessment of both the lower and upper urinary tract. Ultrasonography can be difficult to perform in patients who are not cooperative. Assessment of the fetal urinary tract is part of all routine prenatal ultrasound examinations. Dilatation of the renal pelvis and fluid filled areas as small as 1–2 mm may be visualized *in utero* using high-resolution real-time ultrasound. Most clinically relevant urinary tract obstructions are currently detected in the second trimester. A fetal pelvic dilatation of > 3 mm during the second trimester and > 6 mm after 32 weeks of gestation is considered abnormal. Postnatal evaluation is recommended in all cases of prenatal hydronephrosis. In congenital obstructive uropathy, a renal ultrasound should be performed within the first week of life and repeated 4–6 weeks later. The first postnatal ultrasound should not be performed within the first few days of life, when the kidneys produce little urine. This can mask hydronephrosis and give rise to false-negative results. After the first week postdelivery, a renal ultrasound should be performed in term infants with both a full and an empty bladder; the sonographer should assess renal pelvic dilatation, calyceal dilatation, pelvic or ureteral wall thickening, and signs of renal dysplasia. In the absence of calyceal dilatation, the degree of obstruction is minimal. In these patients functional imaging such as a nuclear renal scan is not recommended. In contrast, dilatation of all renal calyces suggests a greater degree of obstruction, even with less renal pelvic dilatation. The renal pelvis diameter should be measured in the transverse plane and at the anteroposterior diameter. An anteroposterior diameter (APD) of >7 mm in a newborn is considered abnormal (in an older child >1 cm is abnormal). All measurements should be adjusted to age and size and compared with normal values. Pelvic dilatation is often used as an indicator of severity, yet may be overestimated with an extra-renal pelvis, which is clinically irrelevant. It is important to examine the contralateral normal kidney for hypertrophy, which is an important indicator for decreased function in the obstructed kidney.

The combination of APD and diffuse calyceal dilatation at first postnatal ultrasound can distinguish patients with a moderate degree of hydronephrosis who have a higher risk for requiring surgery to relieve urinary tract obstruction. A study of 348 children with antenatal hydronephrosis demonstrated that the predictive capability of this combination was 14-fold better compared to APD alone for patients with APD at 9–15 mm or greater [84]. The absolute percentage difference of ipsilateral and contralateral renal lengths appears to be an additional predictor of the need for pyeloplasty in UPJO [85]. A prospective study of 213 infants found that postnatal ultrasound testing as 5 days and 1 month after birth had high sensitivity and negative predictive value for significant urological disease. Moreover, if two sequential postnatal ultrasound tests showed normal kidneys and urinary tract, only 3% of patients had will have any pathology, which was usually low-grade vesicoureteral reflux [86]. In infants with postnatal APD $\leq$7 mm and no calyceal, kidney, ureteral, or bladder pathology, there is no need for long-term follow-up [87]. If necessary, further investigations include a voiding cystourethrogram, nuclear scan, and (rarely) magnetic resonance imaging to detect and determine degree of reflux and/or obstruction.

Voiding Cystourethrogram

The voiding cystourethrogram (VCUG) is an essential part of most basic evaluations of patients with hydronephrosis. The VCUG provides anatomical information in terms of bladder morphology, bladder capacity, patency of the urethra, bladder emptying, and in case of reflux an anatomical description of the upper urinary tract. It still serves as the gold standard for detecting posterior urethral valves, vesicoureteral reflux, ureteroceles, and bladder diverticulae (Fig. 1). Vesicoureteral reflux can both cause and coexist with hydronephrosis; it can contribute to additional obstruction due to ureteral dilatation and should be assessed early. Grading of reflux can be difficult if obstruction is present. Because of

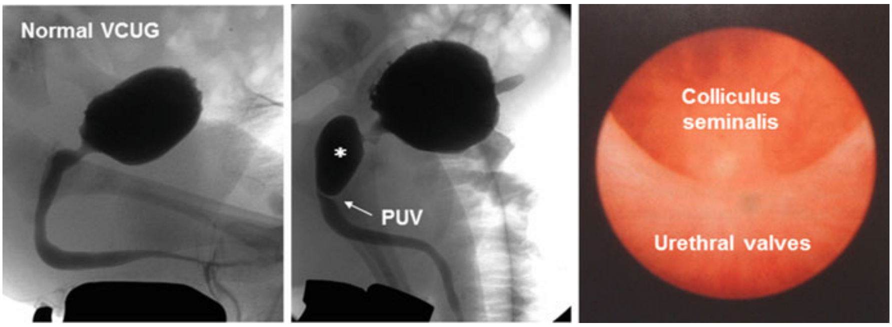

Fig. 1 Posterior urethral valves (PUV) on a voiding cysturethrogram with dilated posterior urethra (*). Endoscopic image of PUV (Courtesy Dr. B. Kammer, Dept. Radiology and Dr. H. G. Dietz, Dept. Surgery, Dr. V. Hauner Children's Hospital, LMU, Munich)

the relatively high incidence of reflux in children with congenital urinary tract obstruction, many physicians keep patients on antibiotic prophylaxis until the VCUG is obtained.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive, radiation-free imaging modality, which is considered ideal for assessment of detailed anatomy, particularly of ectopic ureteral insertion, complicated duplex systems, or when other complex pathologies are suspected. The administration of a specific non-nephrotoxic intravenous contrast medium allows for the functional evaluation of parenchymal perfusion, glomerular filtration, and renal excretory function. Indications for MRI include preoperative anatomic imaging, and the assessment of vascular anatomy. With its fine resolution, the presence of a crossing blood vessel causing obstruction may be detected. The MRI may also differentiate between hydronephrosis and parapelvic cysts. It provides excellent anatomic and functional details of the collecting system. Thus, ureteral strictures in children can be diagnosed more accurately [88]. Its use is restricted in younger children by the need for sedation, its high costs, and limited availability. The correlation with functional outcomes in obstructive uropathy has yet to be established.

Diuretic Renography

Nuclear medicine studies play an important role in the functional assessment of the kidneys. Radionuclide scintigraphy can evaluate relative renal function, estimate absolute renal function, differentiate between functional renal parenchyma and renal scars, estimate renal blood flow, and measure excretory function [89, 90]. Several radiopharmaceuticals are available to image the kidney and monitor function. ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA), ^{99m}Tc-dimercaptosuccinic acid (DMSA), and ^{99m}Tc-mercaptoacetyltriglycine (MAG-3) are the most commonly used radionuclides. In children with obstructive uropathies, ^{99m}Tc-MAG-3 is the main radiopharmaceutical for renal imaging. Following intravenous administration ^{99m}Tc-MAG-3 is highly protein-bound and removed from the plasma primarily by the organic anion transporter 1 located on the basolateral membrane of the proximal renal tubules in the kidney. ^{99m}Tc-MAG-3 accumulates in proximal tubular cells and is secreted into the tubular lumen via organic anion transporters on the apical membrane. If the apical transporter is impaired to a greater extent than the basolateral transporter, ^{99m}Tc-MAG-3 activity is retained in the kidneys. In general, the amount of tracer uptake in the first 2 min after injection correlates with the glomerular filtration rate. The ^{99m}Tc-MAG-3 scintigraphy sometimes described as tubular extraction rate can be used as a measure of relative renal function. Relative renal function is indicated as the relative percentage of the right and the left kidney function. While each kidney normally contributes 50%, due to error, relative renal function is not typically considered to be abnormal until it is < 40%. Decreased renal function either reflects unilateral renal impairment or congenital anomalies (e.g., dysplasia). Normal relative function results may be also obtained with bilaterally damaged kidneys. Because of its efficient extraction (more than twice that of ^{99m}Tc-DTPA), ^{99m}Tc-MAG-3 is preferred in patients with suspected obstruction and impaired kidney function. Multiple protocols have been used for ^{99m}Tc-MAG-3 nuclear scans with different time points of furosemide administration and variable acquisition times [89, 90]. The "F=0 protocol" is the most convenient protocol, in which furosemide (1mg/kg with a maximum dose of 20 mg in a child) is administered simultaneously with the tracer. The "F+20 protocol" involves giving furosemide 20 min after administering the radionuclide that then allows for the direct evaluation of the tracer-washout. The washout phase is used to examine the severity of obstruction; it is conventionally assessed by measuring the half-time (T1/2) after furosemide administration.

The nuclear scan report describes a ^{99m}Tc-MAG-3-time-activity-curve for each individual kidney. The normal curve shows a steep rise, followed by an early peak and a rapidly declining phase. In contrast, urinary tract obstruction with dilatation results in a continuously rising curve. The application of furosemide is used to differentiate between obstruction and "reservoir effect." The time required to clear one-half of ^{99m}Tc-MAG-3 is monitored in minutes (T1/2). A half-time <10 min is considered normal, 10–20 min is uncertain, and >20 min is consistent with obstruction (Fig. 2). That said, a prolonged T1/2 should never be the sole criterion for diagnosing obstruction. Clinical correlation with ultrasound is mandatory and sequential nuclear scans may also be helpful. The Santa Fe Consensus report recommends a 35-min acquisition with furosemide administered 20 min after the tracer. This diuretic MAG3 renography with the "F+20 protocol" is the method of choice in young children with obstructive uropathy. In addition, criteria have been developed for children that allow the furosemide administration to be omitted when the baseline drainage is normal [91]. ^{99m}Tc-MAG-3 scintigraphy can be used as early as at the end of the first week of life to assess differential renal function. Because immature nephrons of the newborn kidney are less sensitive to furosemide, a diuretic ^{99m}Tc-MAG-3 study should be postponed until the patient is at least 4–6 weeks old to allow for nephron maturation. In the typical patient with unilateral hydronephrosis and dilated calyces, ^{99m}Tc-MAG3-scintigraphy would be performed at 2–3 months of age and repeated 3–12 months later depending on the initial results obtained (see Fig. 3 with proposed algorithm for therapeutic approach to postnatal asymptomatic hydronephrosis, adapted from [92]). Patterns of change over time are probably the most useful markers to indicate the status of the affected kidney.

Other tracers, outside of ^{99m}Tc-MAG-3 can also be used

^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA) is the only renal radiopharmaceutical available for routine imaging that is purely filtered by the glomerulus. Consequently, it can be used to measure glomerular filtration rate. ^{99m}Tc-dimercaptosuccinic acid (DMSA) is an excellent cortical imaging agent that is used primarily to evaluate relative function, pyelonephritis, and renal scarring [93]. Approximately 40% of the injected dose is retained by the renal tubules within 1 h after injection. ^{99m}Tc-DMSA initially binds to α_1-microglobulin; the complex is then filtered by the glomerulus and accumulates in the kidney via megalin/tubulin-mediated endocytosis in the proximal tubule [94]. Thus, the renal uptake of ^{99m}Tc-DMSA depends on renal blood flow, glomerular filtration, and proximal tubule receptor-mediated endocytosis. In summary, nuclear scans remain the "gold-standard" assays for the functional assessments of the kidney with obstruction, although better diagnostic tools are clearly needed.

Excretory Urography and Pressure Perfusion Studies

The intravenous pyelogram (IVP) has practically vanished, except for rare circumstances and conditions such as urolithiasis or pre- and postoperative evaluation in complex conditions, particularly when other imaging tools are not available or applicable. In selected cases, in which the anatomy is not

satisfactorily defined, the IVP can provide structural and functional information of the urinary tract. The "Whitaker test," which was developed in the late 1960s and early 1970s, combines an urodynamic study with antegrade pyelography to assess potential upper urinary tract obstruction. The test involves instilling contrast directly into the affected kidney and requires general anesthesia. The "Whitaker test" may differentiate between patients with residual or recurrent obstruction and those with dilatation secondary to nonobstructing permanent ureteral changes. In selected cases it can be used to determine when percutaneous nephrostomy tubes can be safely removed in postoperative patients.

Ureteropelvic Junction Obstruction

Ureteropelvic junction obstruction (UPJO) is the most common cause of prenatal obstructive hydronephrosis and has an incidence of 1 in 1000–1500 newborns. UPJO is more common on the left side (2:1 – left to right) and more common in boys (2:1 – male to female). Bilateral obstruction is rare. UPJO is characterized by an obstruction at the proximal portion of the ureter where the pelvis narrows into the ureter. The obstruction can be classified as intramural, mural, or extramural. Intramural causes are exceptionally rare in children and include abnormal mucosal valves or fibroepithelial polyps. Mural obstructions, which are most common, result from a dysfunctional or adynamic ureteral segment that has an abnormal distribution of smooth muscle cells and collagen fibers. The main proposed mechanisms for the development of mural UPJO are failure in the development of the renal pelvis, abnormal pyeloureteral innervation, and impaired smooth muscle cell differentiation [95]. In mural UPJO the lumen is almost always patent, albeit narrow and irregular. Extramural or extrinsic causes, which are less common, include aberrant or crossing renal vessels, artery and/or vein, bands or adhesions. Usually a lower pole renal vessel fixes the ureter in position; however, not all "crossing vessels" are obstructive. These vessels may also cause intermittent reductions in urine flow leading to intermittent dilatation of the pelvis. In the majority of UPJO the underlying cause is thought to be functional (i.e., mural).

Development of the Ureter and the Ureteral Peristaltic Machinery

The kidney starts to produce urine at ~10 weeks of gestation. At the same time, the trunk of the ureteric bud starts elongating without branching to form the early ureter. Similar to the kidney, the morphogenesis of the ureter requires a close interaction between the inner ureteral epithelial cells and the surrounding ureteral mesenchymal cells. In response to the molecular signals from the epithelial and mesenchymal cells, the early simple cuboidal ureteral epithelial cells differentiate into the multilayered urothelium (also called transitional epithelium). The urothelial surface is covered by urothelial plaques expressing uroplakin proteins and is impermeable to urine [46]. Meanwhile, the mesenchymal cells differentiate into stromal cells, smooth muscle cells, and adventitial fibroblasts (eventually becoming the serosa). Differentiated smooth muscle cells are organized into layers with inner circular and outer longitudinal orientations and express α-smooth muscle actin [49, 54]. Interestingly, ureter smooth muscle differentiation occurs in an ascending fashion from the distal ureter close to the bladder to the proximal ureter that is attached to the renal pelvis. Peristaltic waves are initiated in the renal pelvis and are propagated through the ureter wall to the bladder. Periodic coordinated sequential contractions of the pelvis and ureter are controlled by two distinct populations of urinary tract pacemaker cells (PMCs). PMCs at the pelvic-kidney junction are characterized by expression of hyperpolarization-activated cyclic nucleotide-gated channel 3 (HCN3) and low-voltage-gated T-type calcium channel TTC (also termed CaV 3.1) [57, 96]. Urinary tract PMCs located adjacent to the smooth muscle layer in the proximal ureter are termed Interstitial Cells of Cajal-like cells (ICC-LCs) and express cKIT. The ICC-LCs are located sparsely throughout the ureter (including renal pelvis, UPJ, UVJ) [97]. However, the distribution of ICC-LCs is not even, with most ICC-LCs located in the proximal renal pelvis and reduced cell density in the distal segments of the ureter. The ICC-LCs can produce electrical slow-wave potentials that control the propagation of the peristaltic activity. The molecular mechanism and physiological functions of the ureteral peristaltic machinery are still unclear. It has been suggested that HCN3-expressing PMCs in the tip of the renal pelvis act as the primary pacemaker to initiate spontaneous potentials that are propagated and modulated by ICC-LCs to the adjacent typical SMCs in order to trigger intermediate action potentials and ureteral smooth muscle contraction. The ICC-LCs may also produce additional autorhythmicity and can take over pacemaking in the renal pelvis and ureter in the absence of the primary pacemaker activity [97]. Both populations of urinary pacemaker cells are derived from neural crest and can be detected as early as mouse E12.5 in the tissues surrounding the embryonic kidney [98]. Mouse Kit-expressing ICC-LCs are first detected at E15.5 in a subset of renal epithelial cells and cells of the ureteropelvic adventitia. This developmental time point is followed by the beginning of urine production by the mouse embryonic kidney around E16.5 and is well before the initial ureteral peristaltic waves, which are first observed around E18.5 in mice [98]. It is still unclear when the ICC-LCs appear in the human fetal ureter and at what embryonic stage human fetuses start to have rhythmic ureteral peristalsis.

Genetics of Ureteropelvic Junction Obstruction (UPJO)

Weisschuh et al. have described a ureteropelvic junction obstruction phenotype in patients with Axenfeld-Rieger syndrome (Table 2) [99]. The Axenfeld-Rieger syndrome is caused by mutations in FOXC1, a transcription factor of the forkhead family that is highly expressed in the metanephric mesenchyme. In addition, mutations in the transcription factor *FOXF1*, another member of the forkhead box genes, cause the “Alveolar Capillary Dysplasia with Misalignment of Pulmonary Veins” (ACDMPV) syndrome. ACDMPV is associated with ureteral valve-like constriction at the ureteropelvic junction, tortuous ureters, and hydronephrosis [99, 100]. *FOXF1* is located at the same chromosomal locus as *FOXC2*, and is a part of the sonic hedgehog and TGF-β signaling pathway (Table 2) [101]. Other genes in the sonic hedgehog and TGF-β signaling pathways play critical roles in lower urinary tract development and congenital anomalies. Analysis of obstructing ureteric tissue in infants and children with congenital UPJO demonstrated upregulation of hedgehog signaling effectors and stromal genes suggesting that increased hedgehog signaling may contribute to the pathogenesis of human UPJO [102]. Single gene mutations in genes including TBX18, ROBO2, FREM2, HPSE2, AGTR2, BMP4, and ID2 are proposed in the etiopathogenesis of UPJO [34, 95].

Clinical Presentation in UPJO

Prior to using fetal ultrasound, patients with UPJO were identified due to their signs and symptoms. Patients were commonly diagnosed between the ages of 6 and 15 years, with only 14% being identified younger than 1 year of age [103]. Today, most UPJO is detected prenatally, but some may still present later in life with acute flank pain, nausea, vomiting, and abdominal discomfort. Many of these patients are misdiagnosed as having primary gastrointestinal disease. The pain usually results from intermittent obstruction of the urinary tract when the urine flow overwhelms the capacity to drain. The pattern of abrupt onset with severe abdominal pain, nausea, and vomiting, often in the late evening is typical for older children with UPJO. Late-onset hypertension can occur in patients with obstruction [104]. Urinary tract infection (UTI) is an uncommon presentation in UPJO, but if present, may be quite severe requiring urgent intervention and drainage. Vesicoureteral reflux (VUR) should be evaluated in patients with UPJO and UTI, since the incidence of VUR in infants and young children who present with pyelonephritis is higher than any other anomaly of the urinary tract including obstruction. Fortunately, most children with UPJO are asymptomatic and rarely require intervention.

Management of UPJO

The majority of patients with UPJO can be managed conservatively with close observation and serial imaging [92, 105]. This is usually accomplished by regular repetitive ultrasound testing in well-hydrated infants and children using standardized ultrasound grading and pelvicalyceal system measurements, complemented by intermittent ^{99m}Tc-MAG-3 diuretic scans, if the ultrasound demonstrates suspicion of deterioration. The postnatal evaluation of a child with prenatally detected hydronephrosis should begin with an ultrasound, usually between 48 and 72 h after birth, due to transient neonatal dehydration (which can mask hydronephrosis). However, ultrasound testing is recommended earlier in specific cases, such as bilateral hydronephrosis, solitary kidney or a history of oligohydramnios. Spontaneous resolution of hydronephrosis within the first weeks of life has been shown for 17% of cases [106]. Of the remaining infants, 72%, 19%, and 2% demonstrate mild (5–9 mm), moderate (10–15 mm), and severe (> 15 mm) dilatation, respectively [106]. Whereas almost 90% of cases with mild or moderate hydronephrosis resolve or stabilize within the first 2 years of life, the remaining 10% show persistent moderate to severe dilatation. Approximately 25% of infants with severe postnatal dilatation on initial ultrasound will stabilize or resolve to normal or mild dilation, while 50% stabilize with moderate dilatation within the first 2 years. The remaining 25% of initially severely dilated cases will show persistent severe dilatation [78, 106]. Predicting a future need for surgical pyeloplasty in patients with moderate to severe pelvic dilatation is challenging. As discussed above, the combination of APD and diffuse calyceal dilatation at first postnatal ultrasound can predict, as much as 14-fold better than APD alone, those with a moderate degree of hydronephrosis who have a higher risk for requiring surgery to relieve urinary tract obstruction [84].

Overall, in infants with moderately severe to severe hydronephrosis with caliectasis will need ongoing monitoring and functional assessment. This should include a ^{99m}Tc-MAG-3 diuretic renogram to evaluate differential function and wash-out times (Fig. 2). If the initial function is above 45% in patients with a poor drainage pattern, ultrasound evaluation should be repeated at 3 and 12 months. If the initial differential function is between 35% and 45%, follow-up ^{99m}Tc-MAG-3 may be obtained in 3 months. Ultrasound evaluation should be repeated every 3 months. Progressive hydronephrosis, decreasing differential renal function, recurrent urinary tract infections, and/or urolithiasis may suggest the need for surgical intervention (Fig. 3 with proposed algorithm for therapeutic approach to postnatal asymptomatic hydronephrosis grade 3–4). If the initial relative function is below 35%, surgery to relieve obstruction should be considered. Most surgical interventions for UPJO are performed within the first 2 years of life [107]. In the very small group of newborns with severe UPJO, early surgical correction is safe and efficient and should not be postponed [108]. According to a recent meta-analysis including more than 1000 patients, approximately four out of five children with unilateral UPJO may be treated safely with nonsurgical management. However, approximately 25% of all conservatively followed patients that ultimately required surgical intervention later required a second surgical intervention [105]. High-grade hydronephrosis in neonates is unlikely to resolve spontaneously and is often accompanied by a loss of renal function [109]. For children with less severe hydronephrosis, functional imaging is not usually useful unless regular ultrasound detects progressive hydronephrosis with diffuse calyceal dilatation [109]. Ultrasound intervals are usually increased over time, although most children with UPJO are followed until normal. Closer monitoring should be exercised in patients with a higher risk for adverse outcome (bilateral hydronephrosis, solitary kidney with UPJO).

At present, indications for surgical correction of UPJO vary between institutions, countries, and continents. In a retrospective study of 343 children with prenatally diagnosed UPJO that were initially conservatively managed, over 50% eventually required surgical treatment [107]. Advanced skill and experience as well as new surgical techniques have improved surgical results even in very early infancy (e.g., neonatal pyeloplasty, endoscopic, and/or endoluminal pyeloplasty) [92, 108]. Laparoscopic pyeloplasty has been used for over two decades with good results and low morbidity, but still has limited availability in many centers. With the advent of robotic surgical technology, the learning curve for this type of laparoscopic surgery is markedly shortened [110]. The largest to date series on robotic pyeloplasty in infants includes 62 surgeries in 60 patients with a mean age of 7.3 months and a median weight of 8.1 kg. Resolution or improvement of hydronephrosis was documented in 91% of kidneys [110].

The open Anderson-Hynes dismembered pyeloplasty is still considered the gold standard for relief of UPJO. This procedure can be performed in the flank position or through a dorsal lumbar incision, both of which are cosmetically reasonable. The procedure includes the resection of the stenotic segment, some size reduction of the dilated pelvis, and re-anastomosis of the ureter to the renal pelvis. Success rates are in the 95–97% range. Following UPJO surgery, recovery is quick in infants but slower in older children. Percutaneous nephrostomy (PCN) was more regularly performed one or two decades ago, particularly in neonates with “gross dilatation” as “bridging” until surgery. Today PCN is typically restricted to untreatable pyonephrosis, severe bilateral obstruction with renal insufficiency, or in a severely obstructed single kidney with elevated serum creatinine.

Biomarkers in UPJO

The lack of precise and reliable biomarkers for severity of urinary tract obstruction is problematic [111]. Numerous urinary biomarkers (TGF-β, TNF-α, N-acetyl-β-D-glucosaminidase, Epidermal Growth factor (EGF), CCL2, angiotensinogen, Prostaglandin reductase 1 (PTGR1), Ficolin-2, Nicotinate-nucleotide pyrophosphorylase, Immunoglobulin superfamily containing leucine-rich repeat protein (ISLR), vascular cell adhesion molecule-1 (VCAM-1), metalloproteinases, antimicrobial peptides, and polyomavirus) and serum metabolomics have been evaluated in patients with UPJO [112–122]. The detection of urinary polypeptides by capillary electrophoresis and mass spectrometry (CE-MS) was shown to help predict the outcome of infants with UPJO [123, 124]. A recent meta-analysis included 14 studies with reported data on 380 UPJO patients who underwent surgery, 174 who were treated conservatively, and 213 controls. The authors concluded that some biomarkers offer promising results, but acknowledge that more multicenter, prospective studies are needed to evaluate their diagnostic and prognostic value [125].

Long-Term Follow-Up in UPJO

The long-term outcome is usually positive for most patients with UPJO. Nevertheless, long-term studies have been sparse. Many children undergoing successful pyeloplasty are lost for follow-up after several years. In light of the experimental evidence, as well as the limited clinical data, it is very likely that some of these patients will develop proteinuria, hypertension, or chronic renal insufficiency. In one long-term follow-up study of children after pyeloplasty for UPJO, renal function measured by nuclide scan improved in all but one patient, but was persistently abnormal in 14 of 33 patients [126]. Renal function improved significantly in children undergoing surgery at <1 year of age, but normalized in only one of six patients >1 year of age [126]. Children undergoing pyeloplasty for grade IV hydronephrosis showed a broad range of renal interstitial fibrosis [114]. Delay of pyeloplasty in these children was associated with greater macrophage infiltration, and a lower glomerular filtration rate [114]. In addition, renal interstitial fibrosis can be found in kidney biopsies of UPJO patients and correlates significantly with the differential function of the affected kidney [27]. Differences in the urinary peptidome excretion at 5-year follow-up may indicate permanent changes in the kidney or urinary tract in nonoperated patients with UPJO, while based on clinical parameters alone these children appear to have normal kidneys [127]. These data strongly support the need for long-term follow-up, even in less severe cases of UPJO. For the long-term prognosis it will be important to determine whether these changes are deleterious or the result of an ongoing and possibly beneficial remodeling process.

Ureterovesical Junction Obstruction

Ureterovesical junction obstruction (UVJO) is characterized by an obstruction at the distal end of the ureter where it meets the bladder and results in a megaureter. The term obstructive megaureter or primary obstructive megaureter (POM) is often used for this entity, and should be distinguished from a refluxing megaureter. UVJO is usually caused by an adynamic segment of the distal ureter. Similar to UPJO, histological studies show changes of disordered smooth muscle cells and abnormal collagen deposition. UVJO is less common than UPJO and is reportedly responsible for 9–14%of the cases of hydronephrosis.. UJVO is seen more often in boys and is usually unilateral with more left-sided involvement.

Pathogenesis of UVJO

The "bud theory" developed by Mackie and Stevens explains that the ureteral orifice derives from the original ureteric budding site on the Wolffian duct during embryologic development [128]. When the ureteric buds arise at abnormal sites of the Wolffian duct, the final sites of the ureteric orifices may be also abnormal, resulting in disturbed ureterovesical junctions, vesicoureteral reflux, or UJVO. In addition, multiple ureteric buds may also lead to short duplex ureters, duplex kidneys, and ectopic and dysplastic kidneys [24, 43, 128, 129]. Therefore, mutations of genes controlling early ureteric bud formation and positioning can cause ureteral phenotypes such like urinary obstruction, vesicoureteral reflux, and hydronephrosis [129, 130]. Additionally, maldevelopment of the ureter and its peristaltic machinery may cause UVJO as well (see section "Development of the Ureter and the Ureteral Peristaltic Machinery").

Clinical Presentation in UVJO

Most UVJO is detected prenatally. Urinary tract infection is a frequent clinical presentation of UVJO and should prompt evaluation for additional vesicoureteral reflux in infants and young children. Many physicians keep patients with UVJO on antibiotic prophylaxis during the first 6–12 months. During acute infection, the megaureter may appear far more dilated than before, which is presumably due to the effect of bacterial toxins on the ureteral muscle tone. Abdominal or flank pain, nausea, and vomiting are less common in UVJO.

Diagnosis and Management of UVJO

Diagnosis of UVJO is usually made by ultrasound. Only rarely may ureteral valves be present that can pose a problem, as they can easily be missed. As with UPJO, most cases of UVJO resolve spontaneously. The pattern of hydroureteronephrosis resolution is cranial to caudal and often the distal dilatation is the last to disappear, which can take years. Isolated distal dilatation as a residue of UVJO may be found in older children and adults. While UJVO was initially often operated early, there is now general agreement that a conservative approach is usually feasible without endangering the kidney. With the conservative approach repeated follow-up ultrasound studies are essential. Monitoring for urinary tract infection, often with uncommon bacteria or atypical pathogens such as fungus, is mandatory. Peristalsis of the obstructive megaureter can be assessed sonographically when using cine loop clips or M-mode tracks and the ureteral inflow jet. For quantification of drainage, a diuretic ^{99m}Tc-MAG-3 scintigraphy with an “F+20 protocol” should be performed with good hydration as well as bladder emptying and upright positioning for assuring maximum drainage. Approximately 10% of UVJO patients will need surgical correction. It is important to differentiate those children who do well with primary reimplantation from those who benefit from temporary diversion by ureterocutaneostomy to enable maturation and retonisation of the ureter.

Megacystis Microcolon Intestinal Hypoperistalsis Syndrome

Megacystis microcolon intestinal hypoperistalsis syndrome (MMIHS) is an extremely rare cause of antenatally detected urinary tract dilatation. MMIHS is a cloacal plate anomaly that is more often seen in females. It is a rare genetic disease with autosomal-recessive inheritance. MMIHS is characterized by a dilated bladder and hydronephrosis in the presence of normal or increased amniotic fluid. Smooth muscle cells in the bladder and distal bowel are dysfunctional. Tissue analysis of patients with MMIHS demonstrates a lack of the alpha$_3$-nicotinic acetylcholine receptor subunit giving a possible explanation for the underlying pathogenesis in some cases.

Prune Belly Syndrome (Eagle-Barratt Syndrome)

Prune belly syndrome (PBS) is a rare lower urinary tract malformation affecting about 1 in 30,000 newborns [131]. PBS consists of a triad of typical features, which include a partial or complete lack of abdominal wall musculature with a dry prune like wrinkly skin appearance of the abdomen (hence the name “prune belly”), the dilation of the proximal and distal urinary tract with hydronephrosis, hydroureters, and a distended thin-walled bladder, and bilateral cryptorchidism. All these signs are present in the neonatal period [132]. The majority of PBS patients are males. Coexisting morbidities include pulmonary hypoplasia, vesicoureteral reflux, abnormalities of the urethra, dysplastic kidneys, which commonly lead to chronic renal failure and kidney transplantation. Mutations in *HNF-1B* and *CHRM3* gene have been described in patients with PBS [133, 134]. The prenatal presentation is similar to posterior urethral valves (PUV). In contrast to PUV, both sexes can be affected in PBS, and the so-called “keyhole sign,” which is typical for PUV, is missing on ultrasound.

Posterior Urethral Valves (PUV)

Posterior urethral valves (PUV) are the most common cause of lower urinary tract obstruction in male infants. They are characterized by the formation of sail-like membrane folds from the verumontanum to the prostatic urethra, which causes severe bladder outlet obstruction exclusively in boys. PUV occur in 1:5000–8000 live births and are observed in 0.003% of fetal ultrasound screenings [135]. PUV are the most common cause of obstructive uropathy leading to end-stage renal failure and as such has high rates of morbidity and mortality [3].

Development of the Bladder and Urethra

Unlike the mesodermal ontogenetic origin of the kidney and ureter, the bladder and urethra arise from the endodermal urogenital sinus after the urorectal septum (i.e., Tourneux's fold) separates the embryonic cloaca into the ventral urogenital sinus and the dorsal rectum. At around 5 weeks of human gestation, the urogenital sinus is further separated into the anterior vesicourethral canal and the posterior urogenital sinus. The anterior portion of the urogenital sinus becomes the bladder, which has an open outflow tract at its apex that is connected to the allantois during early fetal development. This outflow tract is only functional at the early embryonic stage to drain the developing bladder to the allantois through the umbilical cord. By ~15 weeks of human gestation, the bladder separates from the umbilicus that becomes a remnant called the urachus, which is further stretched to become the median umbilical ligament. Concurrently, the posterior vesicourethral canal becomes the pelvic portion of urethra in the male (which has three segments: pre-prostatic, prostatic, and membranous segments) and the entire urethra in the female [136]. The mechanisms by which PUV form is still unclear [137].

Pathophysiology of PUV

The classic form of PUV is found in the prostatic urethra, below or proximal to the verumontanum. Although the precise mechanism of PUV formation is unknown, four theories have been proposed to explain their development. They include hypertrophy of the urethral mucosal folds, persistence and continuation of the urogenital membrane, abnormal development of the Wolffian or Mullerian duct, and fusion of the verumontanum or the posterior urethral roof epithelium [138]. The upstream effects of PUV may be profound, leading to abnormal renal development in the most severe cases. PUV may result in massive hydronephrosis and ureteral dilatation; the bladder can be markedly thickened with muscle hypertrophy and matrix deposition. Severe obstructions are associated with oligohydramnios and pulmonary hypoplasia, which causes high mortality and morbidity.

Genetics of PUV

Recently it could be shown that rare variants in BNC2, encoding basonuclin are implicated in familial autosomal-dominant PUV and cause anatomical blockage of the bladder outflow [139].

Clinical Presentation and Diagnosis

Most patients with PUV are detected prenatally by ultrasonography. The typical findings at second trimester ultrasound are bilateral hydronephrosis, distended bladder, dilated posterior urethra (keyhole sign), and thickened bladder wall in a male fetus. Increased echogenicity and cysts in the fetal kidney by ultrasound testing are suggestive of renal dysplasia. Amniotic fluid volume, associated anomalies, and fetal sex need to be assessed by ultrasound (for prenatal diagnosis see section "Prenatal Diagnosis"). Unless there is consideration for antenatal intervention, there is little change in obstetric management. Early delivery is not beneficial and exposes the child to the risks of prematurity. There are no contraindications to vaginal delivery in PUV. Postnatally, the definitive diagnosis of PUV can be made by VCUG. Older children with PUV that were missed on prenatal ultrasound (or that did not have a prenatal ultrasound test) may present with urinary tract infections, urosepsis, renal failure, or urinary incontinence. In most cases there will be evidence of an abnormality on ultrasound, which can be then confirmed by VCUG.

Management of PUV

The clinical management of PUV continues to challenge pediatric nephrologists and urologists due to the wide spectrum of severity, the variable clinical progression, the inability to predict long-term consequences, and the inability to alter renal damage once it is established.

Prenatal Management of PUV

Early intrauterine shunting (vesicoamniotic or vesicoperitoneal shunt) does not improve outcome and carries the risk of severe complications. Vesicoamniotic shunting was first reported as a potential therapy in 1982. Since then, a few case series have suggested that survival could be improved in fetuses that undergo this procedure [140]. Recently, however, in a randomized trial in the UK, Ireland, and the Netherlands, women whose pregnancies with a male fetus were complicated by PUV were randomly assigned to receive either the intervention (placement of vesicoamniotic shunt) or conservative management [80]. The primary outcome was survival of the patient to 28 days postnatally. Survival was slightly higher in the fetuses receiving vesicoamniotic shunting, but the size and direction of the effect remained uncertain, such that benefit could not be conclusively proven. The results showed that the chance of newborn babies surviving with normal renal function is very low irrespective of whether or not vesicoamniotic shunting is done [80]. Unfortunately, the trial was stopped because of poor recruitment. At present, this prenatal surgical procedure is recommended only in fetuses with relatively unimpaired fetal urine samples (see section "Fetal Urine Analysis"). If untreated, fetal lower urinary tract obstruction carries a mortality rate of 45%, which is mostly from associated severe oligohydramnios in the mid-trimester with pulmonary hypoplasia. The initial management of infants with lower urinary tract obstruction may therefore require respiratory support and intensive care.

Postnatal Management of PUV

In suspected posterior urethral valves early postnatal ultrasound is performed. Perineal ultrasound may suggest valves, but a VCUG is still mandatory. Usually early intervention is necessary to ensure sufficient urinary drainage by catheterization, cystostomy, or percutaneous nephrostomy before transurethral valve resection can be performed. The postnatal management focuses on preventing further renal damage that could arise by urinary tract infections. The commonly observed renal damage in these neonates is usually an irreversible renal dysplasia. Adverse prognostic factors in children with PUV include the gestational age at diagnosis, the presence of VUR, echogenic kidneys at the time of diagnosis, the serum creatinine at 1 year of age (>1 mg/dl), the presence of urinary tract infections, and proteinuria and hypertension later in life. Consistent with these factors, a retrospective analysis of 685 children with PUV diagnosed at a median age of 7 days demonstrated that coincident renal dysplasia carries a 9-fold risk of kidney transplant [141]. Long-term urethral obstruction is potentially associated with cystic renal dysplasia and abnormal renal function (glomerular and tubular). Of those who survive the neonatal period, 25–30% develop end-stage renal disease necessitating dialysis and/or transplantation. Optimal management of the lower urinary tract is essential for preserving renal function. Bladder dysfunction requires close monitoring and regular urodynamic investigations [142]. In some patients, decreased renal concentrating ability will expose the bladder to high urine volumes, which will further aggravate a small capacity, stiff and poorly compliant bladder. Recognition and interruption of this cycle of voiding dysfunction is important. Urinary tract infections in children with PUV carry the risk of further deterioration of kidney function and should be treated promptly.

Abstract

Lower urinary tract (LUT) dysfunction is clinically relevant for three main reasons: (1) it may cause urinary tract infections (UTIs), mainly from the accumulation of residual urine; (2) it may adversely affect renal function from febrile UTIs or high intravesical pressure; and (3) it may cause incontinence and thus substantially lower the child's quality of life.

The function of the LUT is intimately associated with that of the bowel; constipation is both a common cause and consequence of many kinds of bladder dysfunction. Among the types of lower urinary tract dysfunction, *detrusor overactivity* is the main cause of daytime urinary incontinence in childhood. The condition is benign but socially harmful and needs to be differentiated from more serious conditions such as neurogenic bladder or urethral obstruction. The two cornerstones of treatment are urotherapy and eradication of concomitant constipation. Urotherapy includes instructing the child to keep a regular voiding and drinking schedule. If first-line therapy is unsuccessful, anticholinergic medication is often warranted. Another LUT disorder, *voiding dysfunction*, i.e., the habitual sphincter contraction during voiding, is common in children with detrusor overactivity. It may be self-limiting but may also result in residual urine and UTIs and can in severe cases be part of a syndrome indistinguishable from the neurogenic bladder and carry the same risks. A third disorder, *neurogenic bladder dysfunction*, most often caused by spinal dysraphism, is characterized by detrusor sphincter dyssynergia. This condition very often leads to recurrent UTIs and high intravesical pressures, threatening kidney function. The introduction of clean intermittent catheterization has improved the renal prognosis tremendously for the children affected by the disorder.

Background

Definitions and Terminology

Throughout this text, the globally accepted lower urinary tract (LUT) terminology, as outlined by the International Children's Continence Society (ICCS), will be strictly adhered to [1]. The specific terms that appear italicized are defined below:

- *Incontinence* means any involuntary leakage of urine and is divided into *continuous* and *intermittent* varieties, the former denoting the situation when urine is constantly leaking and the latter when leakage comes in discrete portions. The word *intermittent* may be omitted when it is clear from the context that the *continuous* variant is not being referred to.
- *Enuresis* means intermittent incontinence at night while asleep (see Chap. 60 on enuresis).
- *Voiding dysfunction* (or dysfunctional voiding) is the term used when urine flow during voiding is diminished by sphincter contractions. Please note that this term should not be used as an umbrella term for all types of LUT dysfunction.
- The child with *overactive bladder* experiences urgency symptoms (i.e., sudden, unexpected urge to void), with or without incontinence, which is then called *urge incontinence*. The term *detrusor overactivity* is warranted when uninhibited detrusor contractions have been documented via cystometry.
- *Holding maneuvers* are behaviors such as standing on tiptoe or squatting with the heel pressed against the perineum or digital

compression on the genitalia, used by children as an often unconscious response to detrusor contractions. *Voiding postponement* is the term used when these maneuvers are used habitually.

- *Underactive bladder* means that the child needs to strain to void. When insufficient or absent detrusor contractions have been detected cystometrically, the term *detrusor underactivity* may be used.
- When the storage function of the bladder has been assessed using voiding charts, *voided volumes* have been measured. The terms *bladder volume* or *capacity* may only be used when the amount of urine actually inside the bladder has been measured, via ultrasound or catheterization. However, when a standard for comparison is needed, the *expected bladder capacity* (EBC) can be calculated using the formula EBC $= 30 \times (\text{age} + 1)$ mL, which is valid until the adult EBC of 4 dL is reached at age 12 [2].

Tools of Investigation

The use of *voiding charts* is crucial in the evaluation of LUT function in children after they no longer require diapers [1]. A standard voiding chart is created by having the child void in a measuring cup with each micturition for 2 days, and the symptoms such as urgency, enuresis, and daytime incontinence are documented for one or 2 weeks. Ideally, bowel movements and stool consistency (e.g., Bristol Stool Scale) should also be included. Crucial data that can be extracted from the voiding chart include micturition frequency, maximum and average voided volumes (preferably expressed as a percentage of EBC for the child's age), and symptom frequency. The use of voiding charts is strongly recommended in the evaluation of any child with incontinence or other LUT complaints as this provides objective data for analysis.

For children old enough to void on command, the use of *flowmetry* is beneficial, especially for those with suspected voiding problems (e.g., weak stream or the need to strain to void) or with recurrent urinary tract infections (UTIs) secondary to incomplete bladder emptying or therapy-resistant incontinence. To calculate flowmetry, a child will void on a toilet that measures the flow rate, and immediately afterward, the amount of residual urine still in the bladder is assessed via an ultrasound device. The following uroflow curve types are associated with specific voiding dynamics (see Fig. 1): (1) the bell-shaped curve which is normal, (2) the tower-shaped curve which is either normal or indicative of detrusor overactivity, (3) the staccato curve which indicates dysfunctional voiding, (4) the plateau curve which raises the suspicion of anatomical outflow obstruction, and (5) the intermittent curve which is typical of detrusor underactivity. Residual urine volume in excess of 20 mL is pathological. Please note, however, that a pathological curve needs to be verified by successive flowmetry studies before even tentative conclusions may be drawn.

When a noninvasive screening of the LUT function of infants and children before the age of bladder control is needed, a *4-h voiding observation* is the method of choice [3], if feasible. For this test, the child is allowed to play and eat freely for 4 h while every void is documented by weighing diapers, and ultrasound is used to assessment residual urine volume. If bladder function is normal, there should be at least one complete void without residual urine during the observation period.

Invasive *cystometric evaluation* of LUT function is mainly indicated when the history, physical examination, and/or noninvasive investigation suggest the possibility of neurogenic bladder. Urodynamic evaluation is typically performed by simultaneously measuring bladder pressure via a transurethral pressure-transducing catheter, intra-abdominal pressure via a transrectal probe, and sphincter activity via perineal patch electrodes. The bladder is filled at a slow rate during which pressure is monitored continuously. Variables including presence of overactive contractions, bladder filling pressures, leak point pressure, voiding pressure, post-void residual volume, and relaxation of the sphincter muscle are recorded. These data allow comprehensive evaluation of LUT function.

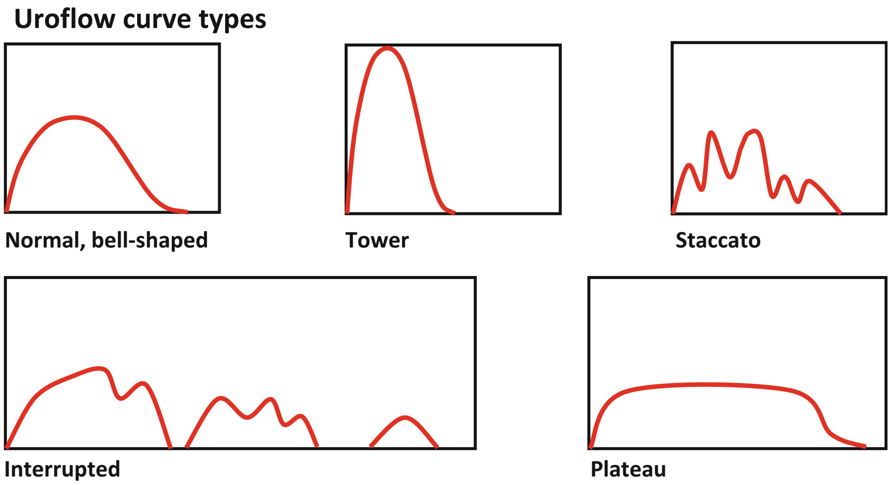

Fig. 1 Uroflow curves

If one suspects constipation, especially if history is ambiguous and rectal examination is not feasible, ultrasonographical measurement of the horizontal rectal diameter behind the bladder can be used. If this diameter is above 30–35 mm in a child without the urge to defecate, then constipation is highly likely [4, 5]. In addition, the Bristol Stool Scale can be used to assess the consistency of stool.

Development of LUT Function

All the neural circuits and pathways for bladder control are present in utero during which urine is voided in small, discrete amounts. The infant is, of course, not socially continent, and bladder emptying is “reflexive”; however, detrusor overactivity is rare, and voiding is usually accompanied by cortical arousal. At the infant stage of development, LUT immaturity with detrusor-sphincter dyscoordination is normal, resulting in interrupted, incomplete voids; however, the bladder is usually completely emptied at least once per 4 h.

The first step toward voluntary bladder control, usually occurring in the second year of life, happens when the child is able to sense and communicate that voiding has occurred or is happening. This phase coincides with bladder enlargement and neural maturation. Next, the child becomes able to postpone micturition for a short while, remaining continent provided a toilet is readily available and an adult is there to help. Subsequently, the child develops the ability to start micturition even when the bladder is not full and no urge to void is sensed. The final stage of bladder control includes the ability to interrupt an ongoing voiding. Complete social continence is achieved by approximately 90% of children by the age of 4–5 years [6]. Children can become continent much earlier by gentle but persistent encouragement of timed voids; [7] this strategy may be recommended for small children with recurrent UTIs. Normal voiding frequency is 5–8 voids per day.

Bladder-Bowel Interaction

It has become increasingly clear that LUT function is very much influenced by the bowel and vice versa. In many children with predominantly urological problems, an underlying bowel issue, e.g., constipation, can be shown to be the main causative factor [8, 9]. There are several potential mechanisms that may explain this link. First, the bowel and the LUT share a large part of their neuromuscular innervation [10]. Second, fecal impaction means that the rectum – which should normally be a signal space, not a storage organ – is fairly constantly dilated and compresses the bladder from behind [11]. Third, behavioral issues such as voiding postponement may not only influence the bladder but also bowel habits [12]. Thus, constipation may be a crucial contributing factor in urinary stasis with recurrent UTIs, detrusor overactivity (with or without incontinence), urinary retention, and voiding dysfunction – including the extreme form severe bladder-bowel dysfunction (see below). Finally, children with neurogenic bladder almost always also suffer from neurogenic bowel disturbance.

According to the Rome IV definition [13, 14], at least two of the following criteria should be present for at least 4 weeks to meet the definition of constipation: (1) two or fewer bowel movements per week, (2) a history of excessive stool retention, (3) painful/hard bowel movements, (4) large-diameter stools that may obstruct the toilet, (5) fecal incontinence once per week or more, and/or (6) the presence of a large fecal mass in the rectum as assessed by ultrasound or rectal palpation.

Conditions

Detrusor Overactivity

Idiopathic detrusor overactivity, often associated with a positive family history, is the most common cause of daytime incontinence. Although there is a clear link to constipation, as mentioned above, the etiology is unknown. Previous notions about urinary incontinence being primarily a psychiatric disorder appear to be incorrect. However, children with daytime incontinence are, for unclear reasons, overrepresented among those with neuropsychiatric disorders such as attention deficit hyperactivity disorder (ADHD); furthermore, incontinence per se may cause low self-esteem and thus secondary psychosocial problems [15].

Invariably, these children experience urgency symptoms, but the problem that makes the family seek medical attention is usually incontinence. Concomitant enuresis (see Chap. 60) is common, as is constipation and/or fecal incontinence. The urinary incontinence typically varies from small wet spots to complete bladder emptying, with and without urgency; furthermore, voiding charts often reveal that these children urinate at the toilet (even ≥ 8 times per day). Holding maneuvers are common. Fortunately, the condition is benign, and most children will have resolution with older age; however, if the child is old enough to be bothered by the incontinence (usually by age six or older), they should be treated (see below).

Dysfunctional Voiding

Dysfunctional voiding (as defined above) may be a learned behavior as a way for the child with detrusor overactivity to manage the involuntary detrusor contractions. In other cases, the pathogenesis is less clear. Importantly, it may also be the first sign of an undetected neurogenic bladder disturbance or be a component of severe bladder-bowel dysfunction (see below) [16, 17]. Patients with dysfunctional voiding will have uroflow studies that consistently show staccato curves. Residual urine is also usually present. As the condition can only be diagnosed by flowmetry, it is unclear how common it is in asymptomatic children. It is usually discovered when investigating a child with recurrent UTIs or therapy-resistant urge incontinence. Patients with this condition are also typically constipated [17]. While dysfunctional voiding may be benign and remit spontaneously, it may also lead to recurrent UTIs secondary to incomplete bladder emptying and urinary stasis and in the worst cases lead to upper tract renal damage. In a child with UTIs and/or hydronephrosis, dysfunctional voiding should be aggressively treated.

Severe Bladder-Bowel Dysfunction

This condition has previously been known as the Hinman-Allen syndrome or non-neurogenic neurogenic bladder [18]. Patients with this condition have voiding dysfunction combined with elevated detrusor filling and/or voiding pressures that are seen in neurogenic bladders, without discernible damage to the spinal cord. Severe BBD may result in an end-stage bladder disease with urinary retention. These patients almost always also have severe constipation, always have high residual urine volumes, and may have upper tract disease. The etiology is largely unknown and probably heterogeneous [17]. In some cases, it may represent the extreme end of the spectrum of learned dysfunctional behavior, starting with ordinary detrusor overactivity, proceeding to dysfunctional voiding resulting in irreversible bladder damage with detrusor underactivity. Rarely, children may have severe BBD from Ochoa syndrome, a recessively inherited condition, characterized by urological dysfunction and the inability to smile [19]. Unfortunately, severe bladder-bowel dysfunction has an unfavorable natural history. It will not remit spontaneously, will often cause recurrent UTIs, and may even lead to end-stage renal disease if left untreated [20].

Neurogenic Bladder

Any damage to the spinal cord, congenital or acquired, can result in neurogenic bladder (and bowel) dysfunction. In children, the most common cause by far is myelomeningocele (MMC). Also, spinal cysts and lipomas that result in spinal cord tethering may be causative. Other causes include malformations such as sacral agenesis or VACTERL syndrome. The LUT of the child with spinal cord damage usually manifests in detrusor sphincter dyssynergia (DSD), i.e., the detrusor and sphincter contractions are not coordinated, which results in high-pressure contractions and incomplete emptying. These problems result in pathological remodeling of the detrusor muscle, which can ultimately lead to poor bladder dynamics that place the kidneys at risk [21]. Although most cases of neurogenic bladder are recognized at birth, some may be detected when evaluating children with recurrent UTIs or therapy-resistant incontinence with noninvasive urodynamics and/or imaging studies. Physical signs that should raise the suspicion of occult spinal dysraphism are lumbar hair tufts or dimples, asymmetrical gluteal cleft, different length of the lower extremities, and/or foot deformities [22].

Although renal function is usually normal at birth, recurrent febrile UTIs and/or high intravesical pressure can often lead to progressive renal failure in the long term, if the LUT (and the bowel) is not treated. Furthermore, many of these children have difficulties reaching continence without expert help. As the child with MMC grows, there is a risk of the spinal cord becoming tethered to the spinal canal, resulting in vertebral deformity (scoliosis), lower extremity deformity, gait, and/or LUT function. A tethered spinal cord should be suspected whenever there is unexplained deterioration of LUT function [23].

Special Conditions

Extraordinary daytime urinary frequency syndrome (EDUFS) is diagnosed in children, usually toddlers, who need to urinate at the toilet very often (more than once per hour) but whose nocturnal bladder function is completely normal for their age. The pathogenesis of the condition is unknown, but the prognosis is excellent [24].

Vaginal reflux, i.e., the entrapment of a moderate amount of urine in the vagina during micturition, may affect prepubertal girls and results in incontinence that consistently occurs shortly after normal voiding. The problem will usually spontaneously disappear by puberty [25].

Giggle incontinence is a rare condition which may be overdiagnosed but also frequently missed. The etiology of this condition is unknown. These patients are typically teenage girls and exhibit urinary incontinence only when laughing. Otherwise, LUT function is completely normal. The condition should be carefully differentiated from both detrusor overactivity, when leakage occurs extra easily when the child's focus is lapsing, and stress urinary incontinence when leakage occurs with pelvic floor laxity during increased intra-abdominal pressure. The leakage in giggle incontinence is linked to laughing only. This condition usually will not remit spontaneously and can be debilitating [26].

Evaluation

The Incontinent Child

Most children with (intermittent) daytime urinary incontinence have overactive bladder. The purpose of the initial evaluation is to differentiate

Table 1 Warning signs in the incontinent child

Signs/symptoms	Possible explanation	Action
Continuous incontinence	Ureteral ectopy	Consult urologist
Poor stream, need to strain to void	Obstruction. Neurogenic bladder. Voiding dysfunction	Noninvasive urodynamics
Stress incontinence	Neurogenic bladder	Noninvasive urodynamics, consult urologist
General symptoms: nausea, weight loss, polydipsia, poor growth	Chronic kidney disease	Urine dipstick, fluid measurements, creatinine, ultrasound
Recurrent UTIs	Residual urine	Noninvasive urodynamics
Lower back findings, leg/buttock asymmetry	Spinal dysraphism	Invasive urodynamics, consider MRI

overactive bladder from other causes, which may lead to different types of treatment signs (see Table 1). The history should focus on the type of incontinence, bladder and bowel habits, development, the presence of general symptoms, and whether the patient has had UTIs. The physical examination should include inspection of the genitals and a neurological examination of the lower limb. The physician should look for signs of spinal dysraphism (see above). Rectal examination is valuable, if feasible, since the presence of formed feces in the *ampulla recti* without a present urge to defecate is virtually pathognomonic for constipation.

The *voiding chart* (as described above) is an essential part of the evaluation of the incontinent child. In addition to providing important LUT data, it can be used to assess the family's adherence and will engage the child and thus form part of therapy.

A *urine dipstick test* is recommended during the initial evaluation of all incontinent children. If leukocyturia is observed, a urine culture is warranted. Please note, however, that asymptomatic bacteriuria – a benign condition that should not prompt antibiotic therapy – is common in children with LUT dysfunction [27, 28]. Thus, in a child with incontinence that is not of recent onset and is not accompanied by dysuria, UTI is less likely a cause for the incontinence, even in the presence of leukocyturia and bacteriuria. However, acute cystitis can cause incontinence from bladder irritability with OAB. Finally, the presence of glucose on urinalysis of a patient with incontinence should prompt evaluation for diabetes mellitus without delay.

Noninvasive urodynamic evaluation is not needed for the initial evaluation unless there are warning signs such as poor stream, need to strain to void, or recurrent UTIs with pyelonephritis. In addition therapy-resistant children should have noninvasive urodynamic evaluation. *Invasive* urodynamics are only indicated if there is a suspicion of neurogenic bladder or if the noninvasive evaluation is consistently pathological.

Daytime incontinence per se is usually not an indication for imaging studies. One would likely perform ultrasound testing of the kidney and upper urinary tracts in patients with general symptoms (nausea, weight loss, polydipsia, poor growth) or a history of febrile UTIs. Ultrasound of the rectal diameter can be useful if there is doubt whether constipation is present or not.

The Child with Abnormal Voiding Frequency, Voiding Difficulties or Urine Retention

A patient with *frequent voiding* often has urgency and as such fulfills the criteria for overactive bladder and should be evaluated in the same way as the incontinent child. A voiding chart including 2 days of urine measurements is important since a minority of these children void often because they have pathological polyuria due to a renal concentrating defect. A urine dipstick test is needed if symptoms started recently or if dysuria is present. Children with EDUFS (see above) require no specific evaluation other than possibly an ultrasound of the bladder to rule out extrinsic bladder compression from fecal impaction or a tumor. A bladder ultrasound test is also warranted to rule out impaction or tumor in children whose symptoms persist or progress for several months.

The patient with *infrequent voiding* is often diagnosed in a child beyond diaper age who has had UTIs. If average voided volumes are significantly elevated (above 130% of EBC for the child's age) or if UTIs are frequent, then noninvasive urodynamic investigation should be initiated. As always, concomitant constipation or bowel dysfunction should be ruled out.

The child with a weak or *poor urinary stream* and/or *urinary straining to void* should be evaluated with noninvasive urodynamics to rule out neurogenic bladder or severe bladder-bowel dysfunction that may pose risks for upper urinary tract and kidney damage. Additionally, these children may have an unrecognized urethral stricture or posterior urethral valves. A screening ultrasound of their kidneys and LUT is useful to evaluate for the presence of hydroureteronephrosis and/or bladder wall thickening. A retrograde urethrogram, voiding cystourethrography (VCUG), or cystoscopy can be selectively used to evaluate patients in whom one suspects bladder outlet obstruction.

The majority of children with *urinary retention* have acquired this as a postoperative complication or are constipated. If the patient has not had surgery and/or constipation is not immediately apparent or if the retention is persistent or recurrent, then ultrasound of the LUT should be performed to rule out fecal impaction or a tumor. A urologist should be consulted, and invasive urodynamics may be indicated.

Other Children Needing Evaluation of Bladder Function

Since most UTIs in children after the age of 2–3 years are caused by LUT dysfunction with incomplete emptying, many children with recurrent UTIs need evaluation of LUT and bowel function. Most recommend that noninvasive urodynamic evaluation (uroflow and residual urine volume) is done in all boys with more than one UTI and all girls with 3–4 or more UTIs. Boys should be evaluated with fewer UTIs since ascending bacteriuria is less common in males and often associated with other congenital anomalies, such as previously undetected posterior urethral valves.

Infants with recurrent UTIs that have associated vesicoureteral reflux (VUR) should undergo 4-h voiding observation (if feasible), since these infants are often not able to completely empty their bladders [29]. *Severe VUR*, i.e., grade IV or V, may be primary and anatomical but may also be secondary to LUT dysfunction. It is advisable to address any LUT dysfunction before correcting the VUR (see Chap. 57 on vesicoureteral reflux). Thus, most recommend that noninvasive urodynamic investigation (4-h voiding observation or uroflow and residual, according to age) be performed in children with high-grade reflux to aid in the management strategy.

Children with evidence of poor renal function of unclear etiology who are found to have hydronephrosis should be urodynamically evaluated, since the poor renal function may be the result of long-standing severe bladder-bowel dysfunction or an occult neurogenic bladder. Noninvasive evaluation of LUT function is required in all children before *renal transplantation*, since untreated poor bladder function may be deleterious for graft function and longevity.

Children with known *spinal dysraphism* need invasive cystometric evaluation in the neonatal period and usually a few additional times later in life. More intensive evaluation is needed when spinal cord tethering is suspected (see above). Most often, patients with suspected occult spinal dysraphism require invasive urodynamics.

Treatment

Children who are distressed by their LUT dysfunction, at risk for recurrent UTIs, and/or at risk for damage to the upper urinary tracts and kidneys should be treated. In most patients, therapy is reserved for those with bothersome symptoms. Those patients that have abnormal voiding chart data or that urinate frequently or seldom with mild urgency or occasional wet spot but are not bothered by these issues need no treatment.

Overactive Bladder

The mainstay of treatment of the child with urge incontinence (urgency being the hallmark of OAB) consists of two strategies: eradication of constipation, if present, and basic bladder advice/urotherapy [30]. Additionally, in the setting of complete bladder emptying, OAB may also be treated with bladder relaxants or antimuscarinics in addition to basic urotherapy. These drugs should not be used when emptying is incomplete.

Treatment of the frequently associated constipation can significantly improve the course of patients with OAB [31]. The child needs to unlearn a maladaptive stool behavior, thus leading to shrinkage of the distended rectum and return of the rectum to function as a signal space, not a storage organ. These behavioral therapies take time, effort, and patience. One frequently used initial strategy is to start with daily mini-enemas (if these are tolerated) for several days, followed by polyethylene glycol daily, with dosage adjusted so that the child has daily soft bowel movements without fecal incontinence. Concurrently, the child is encouraged to keep physically active, hydrate well, consume a healthy diet, and, importantly, never postpone bowel movements. The therapy should continue for a minimum of 3 months [31].

Basic urotherapy includes ensuring that the child orally hydrates well and urinates at the toilet approximately every 2 h (while awake), regardless of feeling the need to void. Voiding body posture should be reviewed with the family including that the child should relax, have support for the feet and thighs, and not rush through visits at the toilet. Voiding schedules and voiding diaries are essential tools for the behavioral-oriented urotherapy. The use of a watch with a vibrating alarm function set for every 2 h is also beneficial, especially when the parents are less available for supervision [32]. Basic urotherapy is usually feasible from age 6 years or older and should be followed for 2–3 months before evaluating treatment success. Approximately half of children treated with basic urotherapy will have resolution of their incontinence [33]; many of the nonresponders appear to have poor outcomes simply because of inadequate adherence to the voiding schedule (and/or bowel treatment). Finally, some children may need the help of a child psychologist or psychiatrist if they have concomitant neuropsychiatric issues.

As noted, OAB with complete emptying or OAB patients who have failed standard urotherapy may require bladder relaxants such as anticholinergic pharmacotherapy to assist with their LUT dysfunction. Many drugs are available, although only oxybutynin has been approved for use in children. Alternative drugs including fesoterodine, tolterodine, and solifenacin appear to have better side-effect profiles and as such are on track for pediatric labeling [34–36]. Before anticholinergic therapy is started, however, the practitioner needs to address several issues: (1) the patient needs to be evaluated for constipation and, if present, treated; (2) significant residual urine needs to be assessed for and addressed if noted; (3) regular micturition habits need to be maintained; and (4) good oral hygiene needs to be ensured. The most common side effect of anticholinergic therapy in childhood is constipation, but there are also risks for incomplete voiding leading to residual urine and, with either constipation or high residual urine volumes, risks for UTIs. Oxybutynin and its metabolites also carry a risk for central nervous system side effects (mood swings, aggression), and most drugs will also diminish saliva production [34]. A typical dosage of oxybutynin is 2.5–5 mg two or three times daily. The effect of therapy is evaluated after 1–2 months. If patients have an initial good response that later diminishes, then constipation should be suspected and treated. If patients develop UTIs during therapy, the drug should be discontinued, and bladder emptying should be evaluated with measurement of residual urine volumes. Likewise, if treatment is needed for long term, then residual urine volumes should be checked every 6 months. Drug tapering is recommended, typically four times per year, to check whether pharmacological treatment is still needed.

Other interventions, outside of anticholinergic drugs, are potentially available to patients. The sympathomimetic drug mirabegron has shown low toxicity and good efficacy as an additional therapy in adults who are nonresponders to anticholinergic monotherapy [37]. More research is needed to determine whether this drug can be used for pediatric overactive bladder [38]. Finally, transcutaneous electrical stimulation, invasive sacral nerve stimulation, and intradetrusor botulinum toxin injections have been used as third-line therapies in cases of severe treatment resistance.

Dysfunctional Voiding

Treatment of dysfunctional voiding is indicated in patients with UTIs or upper tract damage. Care should be taken to exclude neurogenic bladder or severe bladder-bowel dysfunction. After constipation has been ruled out or treated, the first-line therapy is urotherapy with biofeedback [39]. This requires an experienced therapist and collaboration with the child who as a result of training should learn how to distinguish between a coordinated voiding and one with concomitant sphincter contraction. If this therapy is unsuccessful, then alpha-blocker medication may be considered. Severely therapy-resistant voiding dysfunction in a child at risk for UTIs, renal damage, or intractable incontinence should be treated with clean intermittent catheterization (CIC) as in patients with neurogenic bladders.

Neurogenic Bladder or Severe Bladder-Bowel Dysfunction

The treatment of the neurogenic bladder or severe bladder-bowel dysfunction demands the close collaboration between a skilled urotherapist and physicians with pediatric and urological expertise [40]. The cornerstone of treatment is CIC, which should preferably be managed by the child as soon as he/she has attained sufficient maturity. The purpose of therapy is threefold: (1) protection of renal function, (2) prevention of UTIs, and (3) attainment of social continence. For the growing child, the latter of these goals is usually the most important. Almost all children with these conditions will also need aggressive bowel management. If CIC and bowel management alone do not suffice, various additional therapies may be needed, such as intravesical anticholinergics, alpha-blockers, intradetrusor botulinum toxin, or, as a last resort, surgical bladder augmentation and reconstruction of the bladder outlet. Spinal cord tethering will need to be treated neurosurgically [23].

Special Conditions

There are no proven therapies for EDUFS, although anticholinergics, nonsteroidal anti-inflammatory drugs, and behavior therapy have been attempted. Fortunately, most of these children are preschool age, and the prognosis is excellent, regardless of any attempted interventions [41].

Girls with vaginal reflux should be advised to void with their legs held wide apart; one means of achieving this if they are using a western-style toilet is to have the child face the back of the toilet when voiding. If this maneuver does not produce the desired effects, application of a piece of toilet tissue to the perineum with gentle manual pressure after each void usually leads to extrusion of the residual urine [25].

Giggle incontinence is difficult to treat, and as such, patients need to be managed by practitioners with sufficient expertise. Advanced urotherapy (e.g., biofeedback) or off-label use of central nervous system stimulant medication (e.g., methylphenidate) appears to offer the best chances of success [42].

due to the associated myths and negative stigmatization. The aim of this chapter is to provide an updated review of current knowledge on nocturnal enuresis spanning from definitions and epidemiology through new scientific studies on pathogenesis and genetics to internationally accepted protocols for evaluation and treatment. Wherever possible, reference will be made to evidence-based findings and recommendations bearing in mind that low level of evidence is not uncommon in this pediatric field. This chapter complements the data presented in the chapter on bladder disorders (Chap. 58, "Bladder Disorders").

Introduction

Nocturnal enuresis or bedwetting is among the most prevalent chronic diseases in childhood and also represents one of the most feared conditions among children and adolescents due to the associated myths and negative stigmatization. The aim of this chapter is to provide an updated review of current knowledge on nocturnal enuresis spanning from definitions and epidemiology through new scientific studies on pathogenesis and genetics to internationally accepted protocols for evaluation and treatment. Wherever possible, reference will be made to evidence-based findings and recommendations' bearing in mind that low level of evidence is not uncommon in this pediatric field.

Definitions

Enuresis Subtypes

Nocturnal enuresis (NE) is defined by the International Children's Continence Society as urinary incontinence during night while asleep in child aged 5 years or more and with a frequency of at least one episode per month [1, 2]. Although no uniform guidelines are used as to the frequency, many divide NE into frequent (≥4 per week) of infrequent (<4 per week) enuresis and into primary and secondary NE dependent on whether the child has experienced a symptom-free period of at least 6 months [2]. Also, NE is classified into *monosymptomatic* NE (MNE) if the child has no associated lower urinary tract (LUT) symptoms and as *non-monosymptomatic* NE (NMNE) if the child has LUT symptoms such as daytime urinary incontinence, urgency, voiding difficulties (such as poor stream, hesitancy, straining), or abnormal voiding pattern (low or high). The background behind this latter distinction is the fact that bladder dysfunction (such as overactive bladder) is more common in children with NMNE with direct implications on management.

Reduced Bladder Capacity

Reduced storage capacity of the bladder is an important aspect of NE pathogenesis (see below) as well as management and is substantiated by recording voided volumes on a frequency volume chart during 2 days. The observed maximal voided volume (MVV) is compared with age-expected bladder capacity (EBC) (valid until age 12 or max. 400 ml) using the formula:

$$\text{EBC} = (\text{age in years}) \times 30 + 30\ \text{mL}.$$

Reduced MVV is defined as MVV <65% of EBC.

Nocturnal Polyuria

Nocturnal urine production is also a crucial variable in both NE pathogenesis and management and this can be estimated by 1 week of home recording based upon diaper weights and first morning voided volume (nocturnal urine volume = difference in diaper weight before and after sleep plus first morning void). Nocturnal polyuria is defined pragmatically by the International Children's Continence Society (ICCS) as a nocturnal urine volume on a night with enuresis exceeding 130% of EBC of the child. An alternative population-based definition defines age-related polyuria as nocturnal

Table 1 The table shows the age-related reference values for maximal voided volumes (MVV) estimated by frequency-volume charts and for nocturnal urine volume estimated by home recordings (see section "Diaries")

Age	Normal bladder capacity (MVV)	Reduced bladder capacity (MVV)	Nocturnal polyuria on wet night
5 years	180 ml	<117 ml	>234 ml
6 years	210 ml	<136 ml	>273 ml
7 years	240 ml	<156 ml	>312 ml
8 years	270 ml	<175 ml	>351 ml
9 years	300 ml	<195 ml	>390 ml
10 years	330 ml	<214 ml	>429 ml

urine volume exceeding 20 × ((age in years) + 9) ml [3] (Table 1).

Epidemiology

Prevalence

Nocturnal enuresis is worldwide among the most common chronic diseases in childhood and more common in boys than girls (M/F ratio of approximately 1.4) [4], especially in the younger age groups below 12 years [4–6]. The exact prevalence is variably described from 4–24% dependent primarily on different diagnostic criteria used regarding frequency of NE [7]. Thus, prevalence rates are considerably lower in children with more severe enuresis, for example, twice or more episodes per week [8]. Most studies report prevalence in 7-year-olds of 5–10% [8–11] declining to approx. 1–2% in young adults [4]. Although early data indicated a spontaneous resolution rate of approx. 15% annually [12], more recent studies have clearly shown that children with frequent NE have more severe NE [4, 8] and a much lower resolution rate. The exact distribution between enuresis subtypes is not clearly established but one study found that NMNE is more common (approximately 75%) than MNE [13].

Comorbidities and Consequences

Constipation, Fecal Incontinence, and Urinary Tract Infection (BBD)

Although NE is commonly seen alone (MNE) it can be associated with other elimination disorders such as constipation, fecal incontinence and urinary tract infection (UTI), an entity known as *bladder and bowel dysfunction* (BBD)(ICCS). The proportion of NE patients with BBD symptoms is not clear but these patients are important to identify as the risk of underlying anatomical or neuropathic disease is much greater than in NE and management is different (see below).

Behavioral Disorders

Behavioral/psychiatric disorders, such as oppositional defiant disorder, autism spectrum disorder (ASD), emotional symptoms, and in particular attention deficit/hyperactivity disorder (ADHD), are well documented as common comorbidities in NE children, especially in secondary NE and NMNE children [8, 14–16]. The clinical implications are important, as these children are more difficult to treat, show lower compliance, and have less favorable treatment outcomes [17]. Thus, approx. 20–30% of all NE children have at least one behavioral problem, which is twofold higher than in non-NE children [1, 11, 18, 19].

Sleep-Disordered Breathing

Sleep-disordered breathing (SDB) in children comprises a spectrum of sleep-related disorders from intermittent and habitual snoring to severe obstructive sleep apnea (OSA) with a prevalence of 1–5% [20]. Several studies have documented that NE is associated with SDB and OSA as well as asthma, allergic rhinitis, and atopic dermatitis [20–23]. The mechanism behind this is unclear but might involve increased nocturnal urine output [24] through vasoactive hormones and changes in sympathetic and parasympathetic nervous system activity [25, 26]. The clinical implications of SDB are still unclear as controversy exists about the effect of treatment of OSA on NE symptoms [27–29].

Consequences

Nocturnal enuresis is associated with severe negative psychological and social consequences leading to reduced quality of life, loss of self-esteem, social isolation, poor school performance in addition to punishment and domestic violence [30–32]. Interestingly, the reduced self-esteem scores have been shown to return to normal levels after successful treatment [33].

Pathogenesis

Nocturnal enuresis is a multifactorial condition that can be caused by one or more of several mechanisms and with a strong genetic component. A generally agreed pathogenic 3-factor model states that NE is caused by a mismatch between nocturnal urine volume and nocturnal bladder capacity together with an inability to awaken when this occurs (Fig. 1). This model is undoubtedly very simplified but has helped both physicians and families to better understand the nature of the condition.

Sleep/Circadian Rhythm Disturbances

The inability to wake up at the need to void has for ages been translated into the myth that NE children are deep sleepers. An increased arousal threshold to auditory stimuli has supported this hypothesis [34]. Using polysomnography to study sleep patterns in NE children several studies documented that NE usually occurs during the initial hours of sleep but can occur in all sleep stages, most commonly in stage N2, which is not considered deep sleep [35]. More recent cortical arousal analyses derived from sleep studies showed that NE children have a disturbed sleep with many transient arousals leading to sleep fragmentation and poor sleep quality [36–39]. One possible mechanism behind poor sleep quality is periodic limb movements during sleep (PLMS) that has been shown to occur more frequently in MNE with nocturnal polyuria [40, 41]. Interestingly, 6 months successful treatment of NE with the antidiuretic hormone analogue desmopressin was associated with reduced PLMS and improved neuropsychological function on several domains (e.g., working memory) as well as quality of life [42].

Circadian Rhythms

It is now well known that circadian rhythms coordinate our physiology at a fundamental level. The suprachiasmatic nucleus controls the

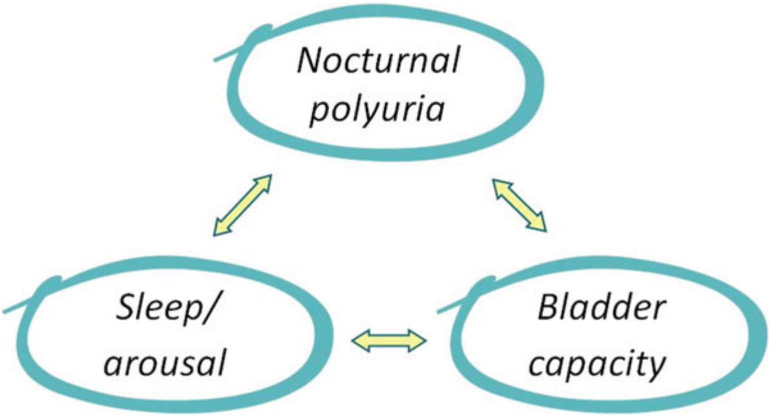

Fig. 1 The main three factors involved in the pathogenesis of nocturnal enuresis. In some children only one factor seems to contribute to the pathogenesis whereas others have two or more factors involved, for example, showing signs of both reduced nocturnal bladder reservoir function and nocturnal polyuria

circadian activity of other oscillators by neuronal and humoral pathways and many circadian clock genes participate in this complex regulation, for example, in bladder and renal tissue [43–45]. It has therefore been speculated that a disturbed circadian rhythm might be involved in NE pathogenesis.

Reduced Bladder Reservoir Function

Bladder reservoir function undergoes significant maturation during childhood involving volitionally control over micturition and an increasing bladder capacity by age until teenage years. There is accumulating evidence that bladder function undergoes circadian rhythmicity with an increased capacity during night, illustrated by the fact that the largest voids in most healthy children are the first morning voids [3]. A significant proportion of NE children (and especially of the NMNE subtype) has clear signs of reduced voided volumes during daytime compared with non-enuretic children, especially in NMNE children [46–51]. Furthermore, some enuretic children with normal voided volumes during daytime show reduced bladder capacity at night only [52]. The background behind this mechanism is not fully understood but may involve central nervous system regulation of bladder function [53].

Nocturnal Polyuria

As early as 1952 Poulton et al. demonstrated an abnormal circadian rhythm of urine output in NE with abnormally large diuresis at night-time [54]. Both in-patient circadian studies and home recordings of nocturnal urine volume later confirmed such defect and related this to a lack of circadian variation in plasma vasopressin with a lack of the normal nocturnal rise [55–61]. These studies showed that increased nocturnal urine output and low levels of plasma vasopressin are related to nights with enuresis and that patients showing this phenotype are characterized by a favorable response to treatment with the vasopressin analogue desmopressin [59]. The mechanisms behind nocturnal polyuria are multifactorial and include decreased urinary concentration [56], glomerular filtration [62], natriuresis [58, 63], and hypercalciuria [64–66]. A possible role of increased nocturnal arterial blood pressure [67–69] and sleep [63, 70] behind nocturnal polyuria in NE has been suggested. Figure 2 shows a possible pathogenic model behind nocturnal polyuria in NE. Future research may further clarify this complex area.

Genetic Factors

Nocturnal enuresis is a highly familial condition illustrated by the fact that 70% of NE children have a positive family history [71] and NE has an estimated twin based hereditability of 67% in boys and 70% in girls [72]. Furthermore, in large single-family studies positive linkage has been established in between NE and several gene loci (4p, 12q, 8q, 13q, and 22q), although no specific gene variations have been identified to date. Very recently, a comprehensive GWAS study including almost 35,000 individuals (3884 NE cases and 31,073 controls) identified six common variants in two different loci (chromosomes 6 and 13) [73]. These findings were replicated in a large Icelandic population and explained approx. 30% of the NE hereditability. Interestingly, the function of the potential risk genes identified (e.g., PRDM13) was related to sleep, urine production, and bladder function.

A common pathogenic hypothesis explaining the possible interrelationships between sleep and arousal, circadian rhythms, bladder function, and urine output regulation is presented in Fig. 2. As all of these mechanisms are under central nervous system control and as most of the involved centers are located in the pontine/hypothalamic region, it is possible that the NE phenotype is defined by dysregulation of one or more of these centers. Future research will test such hypothesis further.

Blood Pressure ↑
AVP ↓
Renal factors
Nocturnal polyuria

Fig. 2 A proposed pathogenic model illustrating the complex background behind nocturnal polyuria in children with NE. Common risk gene variations (e.g., in PRDM13) may increase the risk of dysregulated sleep, circadian rhythm regulation, and bladder dysfunction during night, which can be visualized in sleep studies as PLMS and sleep fragmentation. This can lead to increased blood pressure levels during night resulting in pressure natriuresis and suppression of AVP secretion. Changed autonomic output from the suprachiasmatic nucleus to the kidneys (and other organs) might contribute to the increased urine output during night

Evaluation

History Taking

Several international guidelines and consensus reports exist on the evaluation and treatment of NE [1, 2, 74–78]. In the uncomplicated child with primary NE without the following warning signs:

- UTI
- Constipation
- Severe daytime voiding symptoms such as weak stream and straining (urethral valve)
- Recent onset of secondary enuresis (diabetes mellitus)

Evaluation should be undertaken when the child and family is motivated, usually before school start at 5–6 years of age. History taking is a very important part of NE evaluation aiming to characterize the patient subtype (e.g., MNE vs. NMNE), identify warning signs of underlying disease and other types of incontinence that need to be managed before NE, as well as other comorbidities. Finally, it is important to clarify the social and psychological impact of NE on the child and family and the motivation for therapy. The history should focus on severity and duration of the night wetting, the presence of daytime LUT symptoms (urgency, frequency (>7/day), incontinence, holding maneuvers, straining, interrupted or weak stream), drinking and voiding habits, UTI, urinary tract anomalies, constipation (Rome IV criteria) [79], fecal incontinence, and comorbid psychological disorders (e.g., ADHD). Also, the outcome of previous treatment attempts should be explored. Some guidelines provide checklists for history taking and physical examination [76, 77].

Physical Examination and Other Diagnostic Procedures

In patients with primary MNE without any warning signs (see above) the physical examination is often normal and not revealing [2, 80]. In all other cases or in treatment-resistant patients physical examination should be performed focusing on general health, genital examination, and for signs of occult spinal dysraphism (lumbosacral findings, leg and gluteal cleft asymmetries, abnormal neurology of lower extremities). If the history reveals positive signs of constipation a digital rectal examination (or ultrasound determination of rectal diameter [81]) should be considered, as rectal impaction is an important Rome IV criterion. A urine dipstick examination is only indicated if history or physical examination gives suspicion of underlying disease such as diabetes, UTI, or renal disease. Imaging such as ultrasound of kidneys and urinary tract, voiding-cysto-urethrography, MRI of lower back, and urodynamic investigations are generally not indicated in simple NE but should be reserved for specific patients only.

Diaries

Diaries are very useful tools in the evaluation of children with incontinence including NE, where they can help distinguish MNE from NMNE, reveal inappropriate drinking and voiding habits, and diagnose nocturnal polyuria. All of these might help the healthcare provider to select treatments targeting the underlying mechanism in each child. Ongoing prospective studies are investigating whether such tools indeed result in more favorable treatment outcomes. If such tools are omitted in the initial phase of management, they should be performed in complicated patients, for example, treatment resistance.

Frequency-Volume Charts

In order to estimate daytime bladder function and drinking behavior during daytime a 48-h frequency-volume chart should be performed [1, 82]. This is usually performed during a weekend and record forms can be downloaded from various websites or families can choose to use App versions where recordings can be made directly (e.g., “DryDawn App”). From this tool number of voids per day, maximum and average voided volumes, and total diuresis can easily be calculated. It should be noted, that if MVV is compared to age-related reference values (see section “Reduced Bladder Capacity”), the first morning void should be omitted in the calculation to avoid overestimation [3, 51].

Home Recording of Nocturnal Urine Volume

It is possible with relatively simple measures to estimate nocturnal urine volume in a home setting by weighing the dry diaper at bedtime and repeat this in the morning together with measuring volume of the first morning void. Adding the first voided volume to the difference in diaper weight is a rough but reliable estimate of nocturnal urine volume [82]. This recording should be performed for at least seven nights to give a reliable estimate. It is important to emphasize that in order to diagnose nocturnal polyuria (see section “Nocturnal Polyuria”) only recordings on enuresis nights should be included as nocturnal urine output is usually only high during “wet” nights. The urine output estimates on “dry” nights can be used to identify patients with signs of reduced bladder reservoir function during night-time as such patients would experience enuresis despite low nocturnal urine volume [52].

Other Tools

As the comorbidity with behavioral disorders such as ADHD is rather high and as such comorbidity affects treatment outcome for some treatments and as this is often underdiagnosed, it is recommended to screen for such comorbidity. Abbreviated questionnaire screening tools that can be applied in practice has been suggested and validated [83, 84].

Treatment

First-Line Treatment

Treatment of NE in uncomplicated children can be undertaken in primary care or through school nurses provided that the children are screened for warning signs. After the initial evaluation there are alternative strategies to follow if the family is motivated for treatment. It is important to stress that in NMNE patients daytime symptoms as well as constipation and other comorbidities must be dealt with first (see ▶ Chap. 58, "Bladder Disorders") with the aim of converting the child into an MNE subtype.

Initial treatment for all children with NE should include general advice with explanation of the condition, demystification, and removal of guilt and shame. Also, although regular basic urotherapy has failed to show effect on NE symptoms [85], many would give advice on good voiding habits and fluid intake.

A simple initial strategy consists of a presentation of the assets and drawbacks of the two recommended first-line treatments, that is, the enuresis alarm [86] or desmopressin [87] letting the family decide which option to choose first. If such treatment fails the other first-line option is selected and if both these attempts fail combination of the two first-line treatments can be considered. In most studies, approx. two-thirds of NE patients would respond to such a strategy.

A more extended and personalized strategy involves performing bladder diaries in order to characterize the possible mechanisms behind NE in the individual patient, for example, reduced MVV and/or nocturnal polyuria [2, 76]. In children with reduced MVV and without nocturnal polyuria the alarm system would be the first choice whereas desmopressin would by selected to children with nocturnal polyuria and normal MVV [80]. In children with both factors present a combination of alarm and desmopressin could be tried.

Treatment Resistance

Treatment resistance to either of the first-line treatments can be caused by a number of reasons (Table 2) that should be explored before changing to another modality.

In case of treatment resistance without obvious reason and if no diaries have been performed, it can be of value to do so at this stage. If diaries have been made without treatment, it can be useful to repeat these during ongoing treatment do explore whether the treatment has obtained its effect (e.g., reduced nocturnal urine volume).

Table 2 Some common causes of treatment resistance to the two first-line enuresis treatments, enuresis alarm, and desmopressin

Treatment resistance to enuresis alarm	Treatment resistance to desmopressin
The patient has NMNE or comorbidity (e.g., ADHD)	The patient has NMNE (e.g., overactive bladder)
The patient has both reduced MVV and nocturnal polyuria	The patient has reduced bladder capacity at night
The parents are not waking up the child to an alarm	Lack of adherence to treatment
The alarm is not used every night	Insufficient dosage (e.g., to 240 μg melt)
The alarm has false positive events (e.g., sweating)	Intake later than 1 h before bedtime
The alarm goes off more than once per night	Large fluid/osmotic intake during evening
Alarm treatment was stopped too soon (<8 weeks)	Sleep-disordered breathing (e.g., OSA)

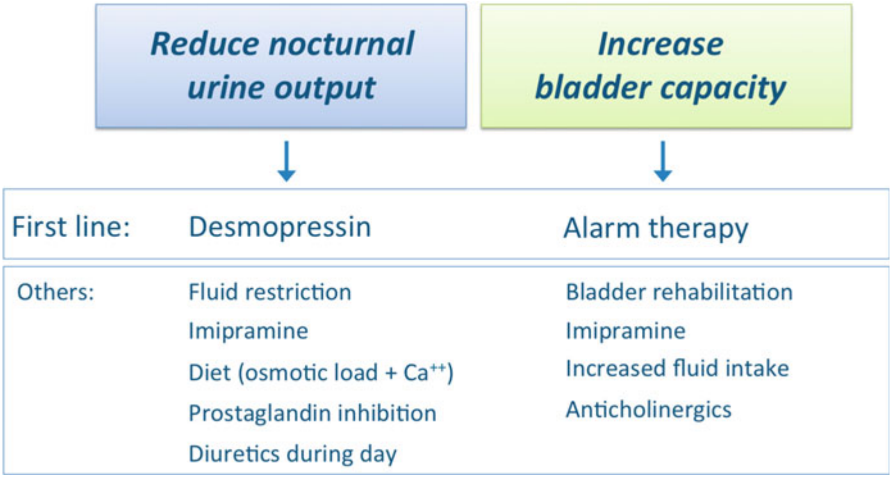

Fig. 3 The main two targets for nocturnal enuresis treatment reducing nocturnal urine output and increasing bladder capacity. The two recommended and evidence-based first-line treatments are desmopressin and the enuresis alarm. Other pharmaceutical treatment modalities include Imipramine, anticholinergics, prostaglandin inhibitors, and diuretics during daytime. Most of these treatments are associated with weak level of evidence. Also, increased fluid intake during daytime with an aim of increasing bladder capacity is advised worldwide despite minimal evidence

As shown in Fig. 3 most treatments for NE can be characterized as targeting either nocturnal urine volume or bladder reservoir function. As mentioned, the two most evidence-based treatments are desmopressin and enuresis alarm probably exerting their main effects on urine output and bladder capacity, respectively. There are, however, other treatment modalities influencing one or both of the two mechanisms and combination therapy using several modalities simultaneously have gained popularity despite the fact that evidence is absent or weak. A recent retrospective study in 59 children with refractory NE reported, however, that 15% showed partial (>50% reduction in wet nights) and 61% full response (>90% reduction) to such a strategy [88]. Imipramine has substantial evidence for efficacy but has potentially lethal cardiotoxicity with overdosing [89]. Anticholinergics have also shown efficacy usually in combination with desmopressin and have shown a more benign safety profile [90]. In most countries NE children refractory to first-line treatments are referred to secondary or tertiary care centers with particular interest and experience in evaluation and treatment of such patients.

Abstract

Clinical aspects of pediatric renal tumors are presented addressing epidemiology, diagnostics, treatments, outcomes, and survivorship. The current chapter is inclusive of the most common pediatric renal tumor (Wilms tumor) as well as less common renal cancers and renal cancer predisposition syndromes.

Keywords

Wilms tumor · Renal Cell Carcinoma · Rhabdoid tumor · Clear cell sarcoma · Nephroblastomatosis

Introduction

Pediatric renal tumors encompass a wide spectrum of disease entities, both benign and malignant, affecting infants, children, adolescents, and young adults. Clinical presentation varies based on age, tumor differential, and extent of disease, but common presenting features include a painless palpable mass, hematuria, fever, anorexia and weight loss, constipation, abdominal/flank pain, and less commonly, respiratory compromise due to anatomical compression or metastatic disease. Care for such children warrants a multidisciplinary approach including but not limited to oncology, radiology, pathology, surgery, and occasionally radiation oncology. Nephrology-centered care may be relevant at any stage of a patient's journey, be it at diagnostics in a child with underlying renal disease undergoing routine scans, post-diagnosis on-therapy navigating underlying renal disease such as hypertension or renal insufficiency as well as consequences of nephrotoxic medications, or posttreatment for management of chronic renal disease, potentially evolving to end-stage renal disease. This chapter will focus on the epidemiology, pathophysiology and biology, radiology and staging approach, treatment, and survivorship issues of infant, children, and adolescents with renal tumors.

Epidemiology

Malignant kidney cancer accounts for nearly 7% of all pediatric cancer in the United States each year. By far the most common renal malignancy is Wilms tumor, accounting for 80% of all suspected renal masses noted on imaging and 90% of all pediatric renal cancers [1, 2]. Other relatively common malignancies include renal cell carcinoma, rhabdoid tumor of the kidney, clear cell sarcoma, and other sarcomas of the kidney. Metastatic tumors spreading to the kidney is rather uncommon in pediatric patients, especially when newly diagnosed with cancer, though not uncommon from Burkitt lymphoma. The chance of having a tumor other than Wilms tumor is higher in

Table 1 Pediatric renal tumors and age at diagnosis [14]

Renal tumor	Age (peak)
Congenital mesoblastic nephroma (CMN)	0–6 months
Ossifying renal tumor of infancy	1–3 months
Rhabdoid tumor of the kidney (RTK)	6–12 months
Wilms tumor (WT) – bilateral	15 months
Nephroblastomatosis	6–18 months
Cystic partially differentiated nephroblastoma	1–2 years
Clear cell sarcoma of the kidney (CCSK)	2 years
Wilms tumor (WT) – unilateral	3 years
Angiomyolipoma	10 years
Renal cell carcinoma (RCC; pediatric)	10–20 years
Renal medullary carcinoma	20 years
Cystic nephroma	Any
"Metanephric" adenoma/fibroma/ stromal tumor	Any

infants less than 6 months of age and children greater than 10 years of age [3, 4] (Table 1).

Benign tumors and tumors with less malignant potential involving the kidney occur at all ages, though are more common in infants and teenagers. Mesoblastic nephroma is by far the most common kidney tumor in newborns. Most patients are cured with surgery, including nearly all with stage 1 and 2 disease, though recurrences occur on occasion, and treated with medical and surgical therapy, leading many to consider such tumors as malignant [5–7]. Cystic nephroma (CN) and metanephric adenoma (MA) can present during childhood, with the potential for CN to be a presenting feature of the DICER1 cancer predisposition [8, 9] and may transform to or be associated with malignant components in some contexts [10, 11], warranting either surveillance or resection.

Investigations into associations of pediatric renal tumors with race have suggested an increased predilection for WT, for translocation renal cell carcinoma (tRCC), and for renal medullary carcinoma (RMC, typically associated with sickle cell trait) in patients of black or African descent [12–14]. Approximately 10% of all pediatric renal tumors overall are thought to occur in the setting of an identifiable cancer predisposition, with identifiable genetic predispositions linked to WT, RTK, CN, RCC, angiomyolipoma, and RMC [15, 16, 68]. Wilms tumor, at times bilateral (approximately 8% of all Wilms tumor) [17, 18] are often associated with overgrowth syndromes (most commonly Beckwith Wideman) [19, 20], WT1 mutation syndromes (Wilms tumor aniridia and growth delay (WAGD), Denys-Drash Syndrome (DDS) or Frazier Syndrome) [21–24], and dozens of other genetic conditions. Interestingly, only 10% of bilateral Wilms tumor cases are identified to be associated with known cancer predisposition conditions, raising question as to etiology of such cases, with undiagnosed genetic as well as developmental biology theories considered (refs above). Specific "familial Wilms tumor" genes have been identified, though account for <1% of all Wilms tumor cases overall [25, 26].

Radiology

The imaging evaluation of a suspected new abdominal mass depends on the patient's age and clinical presentation. In younger children, abdominal radiography and abdominal ultrasound are frequently utilized as the initial imaging tests to confirm the presence of a mass while avoiding the potential need for sedation, which may be required for computed tomography (CT) or magnetic resonance imaging (MRI). In older children and adolescents, ultrasound may still be utilized to evaluate specific clinical signs and symptoms, such as hematuria. However, these patients frequently have nonspecific clinical signs and symptoms and may undergo CT or MRI as their first imaging investigation (Fig. 1).

Abdominal Radiography

Abdominal radiographs in the setting of a suspected abdominal mass are of limited utility. Radiographs can demonstrate alternative diagnoses, such as severe constipation, which can sometimes present as a palpable abdominal mass. Displacement of bowel gas can be a clue that an abdominal mass is present and may indicate the likely organ of origin. For example, mass effect displacing bowel gas away from the left side of the

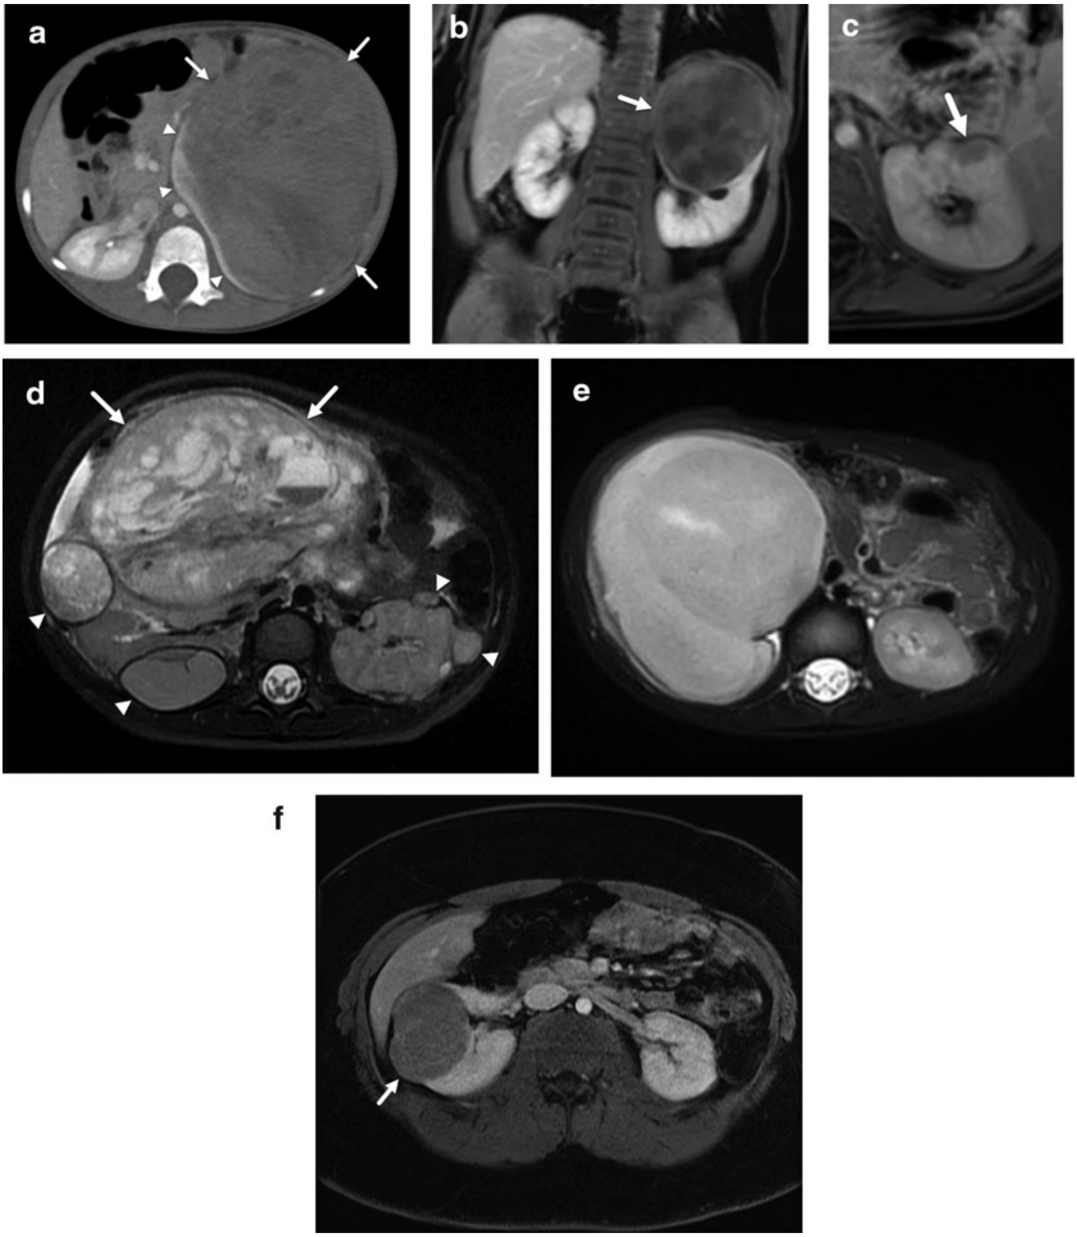

Fig. 1 Imaging features of various renal tumors. (**a**) Wilms tumor. Contrast enhanced CT images in a 3-year-old girl showing a large hypo-enhancing left renal mass (arrows) surgically proven to be a Wilms tumor. Note the "claw sign" with some normal enhancing renal tissue surrounding portions of the mass (arrowheads). (**b**) Wilms tumor. Coronal T1 weighted post contrast images in a 13-month-old boy show a large left upper pole renal mass (arrow) consistent with Wilms tumor. (**c**) Nephrogenic rest. Axial T1-weighted post contrast image in an 18-month-old boy shows a small, homogeneously hypo-enhancing lesion in the left kidney most consistent with a nephrogenic rest (arrow). (**d**) Bilateral Wilms tumor. Axial T2 weighted fat saturated image in a 3-year-old girl show a large heterogeneous right renal mass (arrows) and multiple smaller solid masses in both kidneys (arrowheads). (**e**) Clear cell sarcoma. Axial T2 weighted image in a 16-month-old girl show a large right renal mass which is relatively homogeneous in appearance. The patient underwent right nephrectomy and at pathology the mass was found to be a clear cell sarcoma. (**f**) Renal cell carcinoma. Axial T1 weighted post contrast image in a 14-year-old boy shows a hypo-enhancing, relatively homogeneous right renal mass confirmed to be renal cell carcinoma at resection

abdomen in a younger child most likely indicates a tumor of either left kidney or left adrenal gland origin, while displacement of bowel from the right side of the abdomen could be due to a tumor of the right kidney, right adrenal gland, or liver. Radiographs may demonstrate calcifications, which are more common in certain types of tumors (e.g., neuroblastoma), but are generally not specific. Finally, abdominal radiographs often include a portion of the lung bases. If present, the finding of pulmonary metastases may help to refine the differential diagnosis.

Ultrasonography

Ultrasound should be strongly considered as the initial imaging test in the work up a suspected renal mass or other abdominal mass, especially in younger children. Ultrasound is readily available, is relatively inexpensive, and does not require sedation, intravenous contrast, or ionizing radiation. Ultrasonography can confirm the presence of a mass, and can also exclude alternative diagnoses, such as congenital abnormalities (e.g., a congenital ureteropelvic junction obstruction in a neonate) or infection (such as xanthogranulomatous pyelonephritis). Importantly, ultrasound is also very useful to define the organ of origin of a mass, which may dictate the choice of CT versus MRI as the next imaging test. It is important to note, however, that ultrasound alone is not adequate for staging or for complete tumor characterization, and almost invariably CT or MRI is still required as a next step.

Computed Tomography

Computed tomography (CT) in the setting of a suspected renal mass allows adequate assessment of the primary mass, including size, multifocality, vascular invasion, and complications such as collecting system obstruction. In addition, CT can demonstrate retroperitoneal lymph node enlargement, extrarenal extension, and liver metastases. CT of the chest is the test of choice to evaluate for pulmonary metastases, and can also readily demonstrate intrathoracic lymph node enlargement, if present. The drawbacks of CT imaging include the use of ionizing radiation, the need for intravenous contrast, and the frequent need for sedation in younger children. Importantly, and in contradistinction to some adult CT protocols, a single-phase CT obtained in the portal venous phase is adequate to stage pediatric renal tumors [27]. Routine performance of pre-contrast and delayed imaging adds unnecessary radiation and are rarely, if ever, of diagnostic utility [28].

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has been shown to have equivalent performance compared to CT in terms of the initial assessment of a suspected renal mass in a child [27, 29]. MRI avoids the use of ionizing radiation, but also more frequently requires sedation due to substantially longer imaging acquisition times. Both CT and MRI require intravenous contrast administration. Abdominal MRI may be preferred to CT in certain situations, such as suspected bilateral Wilms tumor. MRI may also be more sensitive for liver metastases and may be used as a problem-solving tool in the setting of equivocal findings of renal vein or inferior vena cava thrombus, as the MRI allows more complete assessment of the vasculature due to superior contrast resolution and the ability to perform multiphase post contrast imaging without the penalty of ionizing radiation. CT is superior to MRI for evaluation of pulmonary metastases.

Nuclear Medicine

Nuclear medicine plays a limited role in the diagnosis and work up of pediatric renal tumors. Assessment of split renal function may assist in surgical planning, especially in the setting of bilateral tumors. FDG-PET typically does not play a substantial role in the evaluation of pediatric renal tumors, except in the setting of late recurrent disease or other rare instances.

Imaging Features of Specific Tumor Types

There is substantial overlap in the imaging features of several of the most common pediatric renal tumors, and frequently patient age and clinical features play a significant role in ordering the differential diagnosis. However, there are some more typical features of certain tumor that may allow a more confident imaging diagnosis.

Wilms Tumor

Wilms tumor typically presents as a large, heterogeneous renal mass. The mass typically demonstrates a "claw sign" – a rim of normal renal tissue that "holds" on to the mass like a claw – which confirms the mass is of renal origin. On ultrasound, the Wilms tumor is usually relatively hypoechoic, but is frequently heterogeneous [30]. With Doppler, the mass frequently demonstrates decreased blood flow relative to the adjacent normal renal parenchyma. US with Doppler can also be used to assess the renal vein and inferior vena cava for tumor thrombus.

With contrast-enhanced CT and MRI, Wilms tumor is seen as a hypo-enhancing mass, usually centered in the renal parenchyma. At MRI, the mass is typically relatively hyperintense on T2 weighted imaging and frequently has areas that show restricted diffusion [30]. Frequently, the mass will have heterogeneous areas of enhancement in the periphery with central hypo-enhancement suggesting necrosis. Involvement of the collecting system is rare but can occur. Both CT and MRI are adequate for evaluation of vascular tumor thrombus [31]. Calcifications, better seen on CT than on MRI, do occur in Wilms tumor but are relatively rare [30]. CT and MRI do not reliably visualize the tumor capsule or extracapsular spread [32]. The sensitivity and specificity of CT and MRI for tumor rupture are also limited. A moderate amount of free fluid, extending above the pelvis, was shown to be the only imaging feature associated with rupture [31]. Tumor rupture cannot be excluded by imaging.

In the setting of bilateral Wilms tumor, MRI with gadolinium containing intravenous contrast is often the preferred imaging modality [27], as MRI may be more sensitive for detection of multifocal lesions. In addition, as these patients typically undergo neoadjuvant chemotherapy prior to any surgical intervention, MRI allows for repeated assessments of treatment response without the exposure to ionizing radiation.

Nephrogenic Rests

Nephrogenic rests are small foci of residual metanephric blastema that persist beyond 36 weeks of gestation [30]. Perilobar nephrogenic rests are more common but have a lower risk of malignant degeneration than intralobar nephrogenic rests [30]. Nephrogenic rests can be difficult to see on US, but may manifest as small oval shaped or round hypo-echoic lesions. On CT and MRI, nephrogenic rests typically appear as small hypo-enhancing lesions, often in the periphery of the kidneys [30]. Unfortunately, imaging cannot reliably distinguish nephrogenic rests from small Wilms tumors. Larger size (over 1.75 cm in diameter) has been shown to be associated with a higher likelihood of Wilms tumor [33]. Additionally, nephrogenic rests tend to be more homogeneous and often have an oval or lenticular shape. Diffusion weighted MRI has been suggested as a possible tool to distinguish between nephrogenic rests and small Wilms tumors, but to date no studies have proven the utility of diffusion weighted imaging in this context [27].

Mesoblastic Nephroma

Imaging features of mesoblastic nephroma can be identical to those of Wilms tumor, typically presenting as a large heterogeneous renal mass [30]. The patient's age at presentation is the most important feature in ordering the differential diagnosis – mesoblastic nephroma is more common in patients under 6 months of age, whereas Wilms is much more likely if the patient is over 1 year of age. The presence of distant metastases and tumor thrombus are also much more likely in Wilms tumor than mesoblastic nephroma.

Clear Cell Sarcoma

These tumors typically manifest as a large, heterogeneous mass that is hypo-enhancing relative to normal renal parenchyma. Clear cell sarcoma may have a more cystic appearance than a typical Wilms tumor on CT. Calcifications are rare but are more common in clear cell sarcoma than in Wilms tumor [30]. In addition, bone metastases are more common in clear cell sarcoma than in Wilms tumor. MRI and nuclear medicine bone scan or PET scan are more sensitive for bone metastases than CT.

Rhabdoid Tumor

At CT and MRI, rhabdoid tumor most commonly appears as a large, heterogeneous mass, more frequently located centrally within the kidney. An imaging feature described more commonly with rhabdoid tumor is the presence of subcapsular fluid, although this finding is neither sensitive nor specific [34, 35]. Calcifications are more common than in Wilms tumor [35]. An association with synchronous and metachronous primary central nervous system tumors has been described.

Multilocular Cystic Renal Tumor

The term multilocular cystic renal tumor encompasses both cystic nephromas, a benign tumor, and cystic partially differentiated nephroblastoma, which contains immature blastemal elements. At ultrasound, these tumors are typically large, with multiple cystic spaces separated by thin septae. Calcifications are rare but do occur [8, 30]. CT and MRI both demonstrate similar findings, with a large multilocular cystic mass divided by thin, uniformly enhancing septa [8]. Solid components are rare, and more likely in the cystic partially differentiated nephroblastoma variant. Multilocular cystic renal tumors frequently have well-defined margins and may have a visible capsule [8, 30]. The tumors have a propensity to “herniate” toward the renal pelvis and collecting system [8].

Renal Cell Carcinoma

Renal cell carcinoma (RCC) is more common in older children and adolescents. In distinction to Wilms tumor, these lesions are frequently smaller in size at presentation, but can still occasionally be quite large. On US, RCC most commonly appears as a round, mildly heterogeneous and hypo-echoic mass. At CT and MRI, the lesions are typically hypo-enhancing relative to normal renal parenchyma and may be exophytic [35]. Heterogeneity may be due to hemorrhage or necrosis. Peripheral or rim-like calcifications may be present [35]. On MRI, RCC is usually iso-intense to mildly hyperintense on T2 weighted imaging, but is frequently heterogeneous, and may demonstrate restricted diffusion [35]. Tumor thrombus can occur and is readily identified on both CT and MRI. Metastatic disease is most commonly seen in retroperitoneal lymph nodes, liver, lungs, bone, and brain.

Renal Medullary Carcinoma

Renal medullary carcinoma is a highly malignant tumor that occurs in adolescents and young adults with sickle cell trait or hemoglobin SC disease. At imaging, the tumor typically appears as an aggressive, infiltrative mass located centrally within kidney. These tumors are typically more irregular shaped and frequently infiltrate the renal hilum, as compared to the more typically round masses seen with Wilms tumor and RCC [36, 37]. Renal medullary carcinoma may infiltrate the collecting system and ureter, and retroperitoneal lymph nodes are frequently involved [35]. Metastatic disease to the lungs is common and may have a lymphangitic pattern as opposed to discrete lung nodules [37].

Screening and High-Risk Populations

In patients with genetic syndromes that predispose to renal tumors, imaging screening is usually accomplished using abdominal or renal ultrasound. While less sensitive and specific than CT or MRI, ultrasound eliminates the need to intravenous access, sedation, and exposure to ionizing radiation (with CT). For example, in hemihypertrophy syndromes such as Beckwith-Weideman Syndrome, patients are typically screened with ultrasound every 3 months for the first 7–8 years of life [19]. Due to the relatively high false positive rate of screening US, an abnormal screening US should be followed by a contrast enhanced CT or MRI. In older children with cancer predisposition syndromes such as Von-Hippel-Lindau, screening with whole body MRI is becoming increasingly more common (Table 2).

In terms of surveillance imaging in patients with a history of a renal malignancy, for the majority of WT patients, chest radiography and ultrasound of the abdomen are replacing traditional use of CT and MRI, based on equivalent survival at relapse independent of modality used [38]. For other renal tumors, CT chest and CT or MRI abdomen remain the imaging tests of choice.

Staging Pediatric Renal Tumors

Pediatric renal tumors, aside from renal cell carcinoma (RCC), share a common pathologic staging system in the United States which differs from that used for renal tumors in adults and is slightly different from the staging system used by SIOP in Europe [39]. This system focuses on the natural history and characteristics of the most common tumor, Wilms' tumor (WT). Most notably, bilateral tumors are assigned a unique stage V with local sub-staging for each kidney. In addition, the friability of WT is such that a biopsy of the tumor prior to nephrectomy automatically merits a Stage III, which is otherwise used for tumor spillage during resection, positive resection margins, and other situations in which tumor is likely to remain within the patient after resection. Stage I, in which tumor is confined to the kidney, Stage II, in which tumor has breached the kidney capsule or infiltrated the renal sinus soft tissues, and Stage IV, in which tumor extends into adjacent organs via hematogenous spread or distant metastasis is observed, are similar to the pathologic staging of other tumors. Details of the Children's Oncology Group (North America) and International Society of Pediatric Oncology (Europe) staging systems for WT are detailed in Table 3.

Table 2 Pediatric renal tumor cancer predisposition syndrome and recommended surveillance

Tumor	Implicated gene(s)	Syndrome	Kidney tumor surveillance	Reference
Wilms tumor				
Overgrowth	11p15, SGB, other	Beckwith-Wideman	Ultrasound every 3 months through age 7 years	Kalish et al. [19]
WT1 and other	WT1, other	WAGR, DDS, Frazier, other	Ultrasound every 3 months through age 5 years	Hol et al. [22] (above)
Rhabdoid tumor	SMARCB1/ SMARCA4	Rhabdoid tumor predisposition	Suggest ultrasound every 3 months through age 5 years + other anatomical targeted imaging	Foulkes et al. [40]
CN (WT, renal sarcoma)	DICER1	DICER1 cancer predisposition	Ultrasound every 6 months until 8 years of age then every 12 months until 12 years of age	Schultz et al. [41]
RCC clear cell RCC; SDHB-associated RCC	VHL; SDHB	Von Hippel-Lindau; hereditary paraganglioma	Annual ultrasound or MRI starting at age 16 (VHL) + other targeted imaging; not established (SDHB)	Chahoud et al. [42]; VHL Alliance
Angiomyolipoma, PEComa/RCC	TSC1/TSC2	Tuberous sclerosis	MRI at diagnosis and then every 1–3 years	Krueger et al. [43]
RMC	Hemoglobinopathy	Sickle cell trait	Not established	

Table 3 Staging pediatric renal tumors

Stage	Children's Oncology Group (COG)	International Society of Pediatric Oncology (SIOP)
I	(a) Tumor is limited to the kidney and completely excised (b) The tumor was not ruptured before or during removal (c) The vessels of the renal sinus are not involved beyond 2 mm (d) There is no residual tumor apparent beyond the margins of excision	(a) The tumor is limited to kidney or surrounded with fibrous pseudocapsule if outside of the normal contours of the kidney. The renal capsule or pseudocapsule may be infiltrated with the tumor but does not reach the outer surface and is completely resected (resection margins "clear") (b) The tumor may be protruding into the pelvic system and "dipping" into the ureter (but it is not infiltrating their walls) (c) The vessels of the renal sinus are not involved (d) Intrarenal vessel involvement may be present
II	(a) Tumor extends beyond the kidney but is completely excised (b) No residual tumor is apparent at or beyond the margins of excision (c) Tumor thrombus in vessels outside the kidney is stage II if the thrombus is removed en bloc with the tumor *Although tumor biopsy or local spillage confined to the flank were considered stage II by NWTSG in the past, such events have been considered stage III in COG studies*	(a) The tumor extends beyond kidney or penetrates through the renal capsule and/or fibrous pseudocapsule into perirenal fat but is completely resected (resection margins "clear") (b) The tumor infiltrates the renal sinus and/or invades blood and lymphatic vessels outside the renal parenchyma but is completely resected (c) The tumor infiltrates adjacent organs or vena cava but is completely resected
III	Residual tumor confined to the abdomen (a) Lymph nodes in the renal hilum, the Periaortic chains, or beyond are found to contain tumor (b) Diffuse peritoneal contamination by the tumor (c) Implants are found on the peritoneal surfaces (d) Tumor extends beyond the surgical margins either microscopically or grossly (e) Tumor is not completely respectable because of local infiltration into vital structures	(a) Incomplete excision of the tumor which extends beyond resection margins (gross or microscopic tumor remains postoperatively) (b) Any abdominal lymph nodes are involved (c) Tumor rupture before or intraoperatively (irrespective of other criteria for staging) (d) The tumor has penetrated though the peritoneal surface (e) Tumor implants are found on the peritoneal surface (f) Tumor thrombi present at resection margins of vessels or ureter, transected or removed piecemeal by surgeon (g) The tumor has been surgically biopsied (wedge biopsy) prior to preoperative chemotherapy or surgery
IV	Presence of hematogenous metastases or metastases to distant lymph nodes	Hematogenous metastases (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdominal-pelvic region
V	Bilateral renal involvement at the time of initial diagnosis	Bilateral renal tumors at diagnosis. Each side should be sub-staged according to the above criteria

Pathology

Wilms' Tumor (Nephroblastoma)

Wilms' tumors (WT) are most commonly unicentric, grossly well-demarcated, and often encapsulated on gross examination, commonly arising from either pole of the kidney rather than the midline. They are generally large and roughly spherical in shape, causing distortion to the renal parenchyma. The cut surface is white-tan to gray in color, soft, friable, and characteristically bulges above the surface once cut. There are often hemorrhagic and necrotic foci, and cystic change can range from a minor component to a dominant feature. Because the tumor is so friable, displacement of tumor cells into spaces or onto the surface of the tumor via "knife metastasis" is nearly inevitable unless proper handling techniques are used [44].

Classic WT are triphasic, composed of an admixture of three histologic elements: primitive, round cells with high nucleus:cytoplasm ratio (the blastema), epithelial elements (predominantly recapitulations of developing kidney such as immature tubules and glomeruloid structures, but includes heterologous epithelium such as squamous), and stroma, which may be relatively undifferentiated spindled cells in a loose myxoid background, or heterologous stromal elements, particularly striated muscle. The tumor may be described as "predominant" in one of these elements if it constitutes >67% of the tumor, or as simply mixed or triphasic. If the classic elements are present, there are few histologic mimics or differential diagnoses for this tumor, though blastema predominant tumors must sometimes be differentiated from lymphomas, neuroblastomas, and other small blue cell tumors that may affect the kidney on biopsies, and other differentials must be considered if pseudo-rhabdoid morphology, rhabdomyomatous differentiation (Fig. 2), or cellular stromal elements dominate.

In approximately 5–9% of cases, anaplasia is found within these tumors. Anaplasia may be defined in WT as nuclei enlarged to three or greater times the size of adjacent nuclei, hyperchromasia, and large atypical mitoses which are suggestive of an increase in chromosomal content. These findings may be seen in any of the three histologic components, though stromal anaplasia alone is rare. Increase in typical mitoses, karyorrhexis, and nuclear enlargement insufficient for anaplasia may be termed "nuclear unrest," which by itself does not carry the same poor prognostic implications as anaplasia. Focal anaplasia is defined as one or more foci with anaplasia which are well defined by surrounding non-anaplastic tumor and no background nuclear unrest. Diffuse anaplasia is characterized by random, poorly defined foci of anaplasia spread throughout the entirety of or a large, undefined area of a WT. Any anaplasia in the presence of background nuclear unrest, or anaplasia in a needle biopsy, metastasis, or extrarenal site is defined as diffuse anaplasia automatically.

Nephrogenic Rests/Nephroblastomatosis

Nephrogenic rests are believed to be remnants of immature/primitive renal tissue which persists beyond approximately 36 weeks gestation when mature renal tissue alone is expected. Perilobar nephrogenic rests (PLNR) are located at the periphery of the lobe (the unit of renal development) and are often well demarcated with predominantly blastemal or epithelial morphology. Frequently these are multiple (known as nephroblastomatosis), often numerous around the subcapsular zone. Intralobar rests (ILNR) are often poorly demarcated, infiltrative lesions in the deep cortex or medulla. These are more likely to be solitary and contain tubular and glomeruloid structures in addition to blastema and stromal elements. Nephrogenic rests are considered precursor lesions to WT, and are noted in 30–40% of WT cases, with up to 98% of cases of multifocal WT arising from NR. Further characterization of both types of NR into dormant/incipient, regressing/sclerosing, and hyperplastic NR may be done based on their histologic appearance, with hyperplastic NR particularly difficult to distinguish from true WT. A true tumor capsule, if seen, is more characteristic of a WT.

Genetics of Wilms Tumor/Nephrogenic Rests/Nephroblastomatosis and Syndromic Associations

Tumor-specific cytogenetic changes, particularly loss of heterozygosity (LOH) for chromosome 1p and 16q and gain of 1q, have been shown to be important prognostic factors which impact overall risk stratification and chemotherapy protocol [45–47]. Investigation of tumors at diagnosis by SNP array or alternative technique is therefore an important element of proper workup.

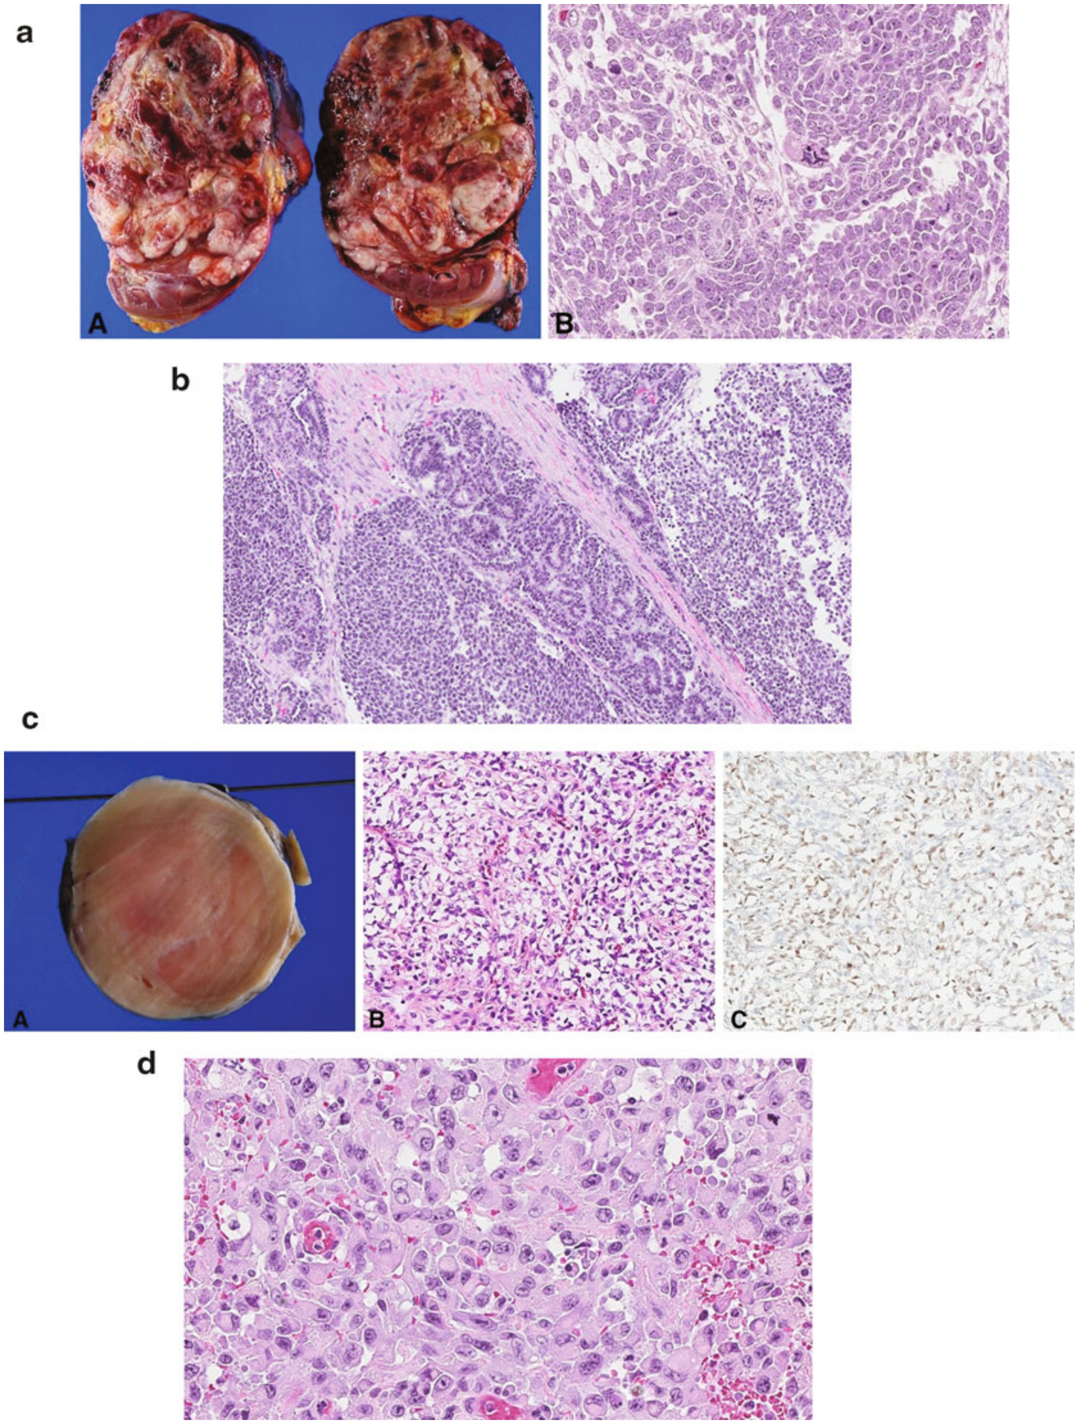

Fig. 2 (continued)

Constitutional perturbations in WT1 and 2p24.3 duplication have been linked to arrest in development of embryonic renal tissue resulting in the development of nephrogenic rests. Subsequent events likely facilitate oncogenesis to a more malignant phenotype. The pathogenesis of WT is complex, however [48]. Greater than 20 WT constitutional/familial predisposition genes, reflecting diverse biological processes, have now been identified, of which the most common are *TRIM28, REST, WT1, CTR9, H19* hypermethylation, *CDC73*, Biallelic *BRCA2*, and Biallelic *NYNRIN*. Additional genes include *ASXL1, DICER1, KDM38, TP53, BLM, BUB18, DIS3L2, PALB2, TRIM37, TRIP13, GPC3* (X-linked), and *Pik3CA* (mosaic) [25]. Subsequent sporadic genetic events in WT resulting in putative driver mutations include but are not limited to mutations impacting nephron differentiation (*CTNNB1, AMER1, MLLT1, SIX1,* and *SIX2*) and mutations affecting microRNA (miRNA) production (*DROSHA, DGCR8*, and *XPO5*) [49, 50]. TP53 mutation, which is more commonly sporadic, is particularly important, as it has been associated strongly with anaplastic histology and may be localized and assessed with immunohistochemistry [51, 52]. For a more complete review of the complex genetic and epigenetic landscape of WT, its pathogenesis, and relationships to renal development, the reader is referred to a current review by Li et al. [53].

Congenital Mesoblastic Nephroma

Congenital mesoblastic nephromas (CMN) are generally large, gray-tan solitary tumors with a soft, whorled appearance to the cut surface. They are poorly defined and appear infiltrative even on gross examination, particularly into the soft tissues of the renal hilum. Completeness of surgical resection is an important prognostic factor so careful examination, particularly of the hilum, is important. By histology, classic CMN are composed of fascicles of relatively bland spindle cells, occasionally showing collagen infiltration. Cysts may be seen, and the mitotic activity is generally low. The tumor is particularly distinctive at the periphery, where tongues of cells extend and infiltrate the surrounding tissue, frequently entrapping native renal structures. Cells of similar morphology but higher mitotic rate with higher cellularity and crowding, resembling infantile fibrosarcoma, constitute the cellular variant of CMN. The cells appear fibroblastic or myofibroblastic on H&E and show positivity for muscle actins and desmin. This tumor may resemble a stroma predominant Wilms tumor, which is less common in the first 2 years of life when CMN is common. It may also be differentiated from clear cell sarcoma of the kidney through subtle features such as entrapping islands of parenchyma at the periphery rather than individual structures. Monophasic synovial sarcoma has a classic immunohistochemical pattern and cytogenetic driver that allows it to be distinguished from CMN.

The cytogenetic driver of this tumor, particularly the cellular variant, is the t(12;15)(p13; q25) translocation producing ETV6-NTRK3 fusion identical to that seen in infantile fibrosacoma. The cellular variant is also frequently aneuploid, with additional copies of chromosomes 8, 11, and 17. The classic variant, on the other hand, shows no characteristic genetic abnormality [54–56].

◀

Fig. 2 (**a**) Favorable histology Wilms tumor (H&E, 170× magnification) – all three components of the classical triphasic WT are seen, including blastemal, epithelial, and stromal elements. Wilms tumor grossly is encapsulated and friable, with foci of hemorrhage and necrosis often seen. (**b**) Anaplasia in a WT (H&E, 400× magnification) is characterized by massive nuclear enlargement and large, bizarre atypical mitotic figures, seen here. (**c**) Clear cell sarcoma of the kidney is grossly well circumscribed without a capsule, and fibrous and firm in texture. CCSK (H&E, 300× magnification) shows classic histology with clearing of both cytoplasm and nuclei, in nests defined by a fine network of capillaries. Positive nuclear staining for BCOR by immunohistochemistry is a common finding. (**d**) Rhabdoid tumor of the kidney (H&E, 400× magnification) shows classic rhabdoid cytologic features, including eccentrically placed nuclei, prominent nucleoli, and eosinophilic cytoplasmic inclusions

Clear Cell Sarcoma of the Kidney

Clear cell sarcomas of the kidney (CCSK) often present as large (2–24 cm) masses that may, if small enough, appear centered in the medulla. They are circumscribed but unencapsulated and may show necrosis, hemorrhage, and cysts. Microscopically, this tumor shows a classic pattern of plump round-oval cells with scant or moderate amounts of pale or clear cytoplasm in nests and cords, separated by myxoid stroma with arborizing vessels. The tumor may also show areas of spindle cell morphology, epithelioid morphology, palisading, sclerosing, pericytomatous, and monstrocellular/anaplastic areas. The periphery of the tumor often appears “scalloped,” with a sense of circumscription at first glance but entrapping individual nephrons, often with cystic dilatation, when the periphery is examined more closely. The tumor shows variable enough morphology to mimic in at least some cases almost every other pediatric renal tumor, though the classic morphology may be found in most cases if sufficiently sampled and searched. It characteristically stains for vimentin, and cyclin D1 is a sensitive, if not specific, marker.

Investigations into the genetic alterations in CCSK show a BCOR internal tandem duplication in many cases and a t(10;17) translocation producing a YHWAE-NUTM2 fusion in other cases, which tend to be mutually exclusive [57–60]. The few remaining cases have rare BCOR-CCNB3 fusion or other rarer abnormalities, and specific immunohistochemistry targeting BCOR is commonly used as a correlate with abnormalities for rapid diagnosis [61].

Malignant Rhabdoid Tumor of the Kidney

Malignant rhabdoid tumors of the kidney (MRT) are roughly spherical with a soft, tan cut surface. Often these are grossly extensive beyond the kidney at diagnosis and have extrarenal metastases at presentation. The classic rhabdoid cytology, described as large epithelioid cells with abundant eosinophilic cytoplasm, a dense hyaline cytoplasmic inclusion a large pale/vesicular nucleus, and a prominent nucleolus, is a significant clue to the diagnosis on histology, though not pathognomonic for it. The tumor is unencapsulated with ill-defined borders and vascular invasion is common. The most common histologic mimic is renal medullary carcinoma, but this tumor may be recognized by the loss of INI-1 by immunohistochemistry.

The loss of INI-1 by immunohistochemistry is a correlate of the bilallelic inactivation of the SMARCB1/BAF-47 tumor suppressor gene on chromosome 22q11–12 that is the driver of these tumors. Since the same inactivation was described in atypical teratoid-rhabdoid tumors of the brain (ATRT), familial inheritance of a germline mutation has been described as the rhabdoid tumor predisposition syndrome. These patients may develop aggressive rhabdoid tumors, including those in the kidney, ATRT in the brain, and other SMARCB1 inactivated tumors such as epithelioid sarcoma of the soft tissue. Few cases of this tumor show inactivation of the related SMARCA4 gene, for which an immunohistochemical stain to detect the loss of the gene product BRG1 has been developed [62, 63].

Treatment

Surgery

Regardless of pathology, surgery is a key component of the management for children with renal tumors. Across pathologies, this often centers on early and complete surgical excision of the primary tumor, where possible. The timing of surgery – whether before or after initiation of chemotherapy – may vary depending on whether treatment occurs according to COG or SIOP protocols. The goals of surgery, across pathologies and COG/SIOP, are largely the same: safe removal of the tumor (with complete excision as possible), avoidance of intraoperative spill, and thorough lymph node sampling [64]. Among very-low risk Wilms tumors (children <2 years of age with stage I favorable histology Wilms tumors less than 550 g), surgery is the sole necessary initial therapy. These patients can be successfully observed without initial chemotherapy with

85% event-free survival and >98% overall survival [65]. There is potential to extend the “upfront nephrectomy followed by observation without chemotherapy” to additional WT subgroups [66].

As to lymph nodes, on study National Wilms’ Tumor Study-5 (NWTS-5), a surgical quality assurance program identified that lymph node sampling was not performed in 9% of WT cases, and that for 41% of stage III patients, nodal positivity was the sole factor that up-staged the patient to local stage III [67, 68]. The importance of lymph node sampling extends to other pathologies besides Wilms tumor as well [69, 70], including translocation-associated renal cell carcinoma (tRCC) which has high rates of nodal positivity [13, 71, 72]. Formal lymph node dissection, as opposed to sampling alone, in the management of pediatric RCC remains controversial, with some advocating for complete lymph node dissection while others believe it may not be indicated in the absence of suspicious imaging [73–75].

Particularly important among surgical considerations is when nephron-sparing surgery (NSS) should be utilized for patients with renal tumors, especially favorable-histology Wilms tumor. NSS is a key strategy for preservation of renal mass and function in these patients. Renal failure is rare amongst unilateral non-syndromic patients, with a rate of about 0.6%, but much more common as a long-term complication in patients with bilateral Wilms tumor (BWT) with rates as high as 11.5% [76]. BWT occurs in about 5–7% of patients with Wilms tumor [77]. AREN0534, a study protocol through COG, clarified the approach to these patients with preoperative chemotherapy and surgical intervention by no later than 12 weeks [78]. The use of bilateral NSS has increased in recent years, from rates of 13.8% of patients undergoing bilateral NSS on NWTS-2 and NTWS-3 to 19.4% with NWTS-4, and 35% with AREN0534. This strategy has largely been reserved for patients with BWT, Wilms tumor in a solitary kidney, or unilateral Wilms tumor (uWT) in patients with a predisposition syndrome. With an increase in use of the technique, there has also been an increase in awareness of complications. The most frequent complications after NSS include persistent urine leak, urinary tract infections/pyelonephritis, intestinal obstruction, and intussusception [79, 80]. Increasingly, given the excellent outcomes for favorable histology Wilms Tumor, efforts have shifted to minimizing the treatment-associated morbidity. It is in this context that consideration of NSS for unilateral Wilms Tumor has arisen. Numerous studies, including from SIOP, have demonstrated good results with NSS for uWT [81, 82]. However, these studies have demonstrated a relatively high rate of positive margins (58%) in this population, upstaging patients to local stage III with an impact on intensity of chemotherapy and radiotherapy, which indicates the importance of case selection and technical expertise [83]. Others have shown lower rates of positive margins (23.5%) with no association with local recurrence. Predictive algorithms suggest that only approximately 5% of unilateral FHWT present with features suggesting feasibility of a nephron sparing approach [84].

One key driver of NSS is the preservation of renal mass, and therefore renal function. One series of 17 patients, including 8 with bilateral NSS and 9 with unilateral nephrectomy and contralateral NSS demonstrated ESRD in 3 of 17 patients – including two who were rendered anephric due to further resections for recurrences [76]. All three patients had received radiation secondary to tumor stage or histology. Efforts to understand the impact of renal volume and function have found that patients undergoing NSS with ≥40% preservation of volume had no deterioration in their renal function during adolescence with preserved global renal function within normal values [85]. When comparing patients who underwent nephrectomy with those undergoing NSS (for unilateral Wilms tumor), those undergoing nephrectomy had an eGFR loss of 19.1 compared with an eGFR gain of 28.6 for those undergoing NSS [81]. These findings suggest that NSS results in improved renal function preservation and should be carefully considered in select patients with renal tumors, where surgical considerations and margin status will not compromise oncologic outcomes.

Medical Therapy

Chemotherapy standards exist for WT and CCSK, in both the COG and SIOP. Therapeutic intensity is based on risk stratification variables including tumor stage, histology (favorable vs anaplastic), biology (LOH 1p/16q), and response to initial therapy both radiologically and histologically [47, 86–94]. Using such approaches, many poor prognostic variables can be overcome including LOH 1p/16q, advanced stage in favorable histology Wilms tumor, and anaplasia in low stage patients [95]. Common chemotherapy agents used to treat WT and CCSK, as well as RTK, are listed in Table 4.

Targeted Therapy

With advances in biological understandings and emphasis on personalized targeted therapy, several renal-tumor specific therapies have emerged. First, targeting NTRK with TRK inhibitors is evolving as a potential replacement for chemotherapy for treatment of relapsed/metastatic mesoblastic nephroma [96]. Secondly, targeting mTOR with mTOR inhibitors has proven beneficial in patients with angiomyolipoma, particularly TS-associated [97]. Efforts to identify better biological risk stratifiers (such as gain of 1q [46]) targeted therapies for biologically unfavorable and relapsed WT, RTK, and tRCC are underway [98–100].

Radiation

Due to the relative radiosensitivity of Wilms tumor, radiation has been used for the treatment of both the primary site and metastatic sites. Primary site radiotherapy is guided by local stage as well as histologic considerations. NWTS 1 and 2 demonstrated lack of benefit for radiotherapy in early local stage tumors. NWTS-3 established 1000 cGy as equivalent to 2000 cGy in stage III FH patients when doxorubicin is included. Thus, for FH stage III WT, flank radiotherapy to 10.8 Gy in 6 fractions is standard of care. If there is evidence of peritoneal dissemination via preoperative rupture or intraoperative spillage beyond the tumor bed, then this transitions to 10.5 Gy in 7 fractions directed at the whole abdomen [101]. Results from AREN0321 demonstrate excellent local control rates with the use of

Table 4 Chemotherapy used to treat pediatric renal tumors

Drug	Mechanism	Tumors	Select common side effects (beyond alopecia/nausea/vomiting)
Vincristine	Anti-mitotic; inhibits microtubule assembly	Wilms, CCSK, rhabdoid	Peripheral neuropathy; SIADH
Dactinomycin	Antineoplastic antibiotic – DNA intercalation	Wilms	Myelosuppression, hepatopathy
Doxorubicin	DNA intercalation; topo II inhibition	Wilms, CCSK, rhabdoid	Myelosuppression, cardiomyopathy, mucositis, secondary leukemia
Cyclophosphamide	Alkylating agent	Wilms, CCSK, rhabdoid	Myelosuppression, hemorrhagic cystitis, infertility
Etoposide	Topoisomerase II inhibition	Wilms, CCSK, rhabdoid	Myelosuppression, infusion reaction/ hypotension, secondary leukemia
Carboplatin	Alkylating agent	Wilms, rhabdoid	Myelosuppression, hypersensitivity reaction, hearing loss, kidney injury
Irinotecan	Topoisomerase I inhibition	Wilms	Diarrhea, myelosuppression
Ifosfamide	Alkylating agent	Wilms, rhabdoid	Myelosuppression, hemorrhagic cystitis, infertility
Topotecan	Topoisomerase I inhibition	Wilms	Myelosuppresion, rash
Sunitinib, Axitinib, Cabozantinib	Anti-angiogenic	Renal cell carcinoma	Hypertension, rash, proteinuria

10.8 Gy flank RT for DAWT stage I–II and 19.8 Gy for DAWT stage III–IV. Same consideration for whole abdomen RT to 10.5 Gy should be given in DAWT, with boost required in this histology [86]. Nonetheless, debate exists whether all patients with stage 1 diffuse anaplastic WT require radiotherapy [87, 102].

Whole lung radiotherapy has been established as standard of care in the treatment of WT patients with pulmonary metastases. AREN0533 omitted whole lung radiotherapy in patients with lung metastases for patients who met the following criteria: favorable histology WT, no LoH1p/16q, lung only metastases, and a complete response (CR) in the lungs by week 6 interval disease assessment. The 4-year EFS in CR patients with RT omitted and incomplete responding patients (with RT) was 79.5% and 88.5%, respectively. These numbers were superior to prior studies with omission of whole lung irradiation deemed appropriate in the selected group given known toxicities. Whole lung radiotherapy dosing is 12 Gy in 8 fractions for patients above 12 months of age and 10.5 Gy in 7 fractions for those under 12 months of age [89].

Whole liver radiotherapy is advised for patients with liver metastases, typically dosed to 19.8 Gy in 11 fractions with consideration of focal boost for residual tumor at time of radiotherapy. Consideration can be given to resection or focal radiotherapy alone for cases of solitary liver metastases.

Cardiac-sparring WLI techniques as well as IMRT for whole liver RT have demonstrated both feasibility as well as dosimetric advantages over classic 3D conformal techniques [103].

With the increasing use of nephron-sparring resection, particularly in cases of bilateral Wilms tumor or in patients with predisposing conditions for renal disease, focal radiotherapy techniques have also grown in consideration. This may be an option in cases of positive margin, following resection where classically whole flank RT would be used.

Radiotherapy is also considered standard for stage 2–4 CCSK, stage 1–4 RTK, and may have palliative benefit for managing symptomatic loci of pediatric RCC.

Survivorship

With over 90% of children treated for Wilms tumor surviving their disease, as well as improved cure rates for children with CCSK and low stages of other pediatric neoplasia, addressing late effects of therapy related to surgery, radiation, and chemotherapy is a critical healthcare initiative. The Childhood Cancer Survivor Study (CCSS) reported 25-year follow-up of WT survivors, demonstrating the cumulative incidence of all and severe chronic health conditions impacted two-thirds and one-fourth of WT survivors, respectively. Thankfully, mental health status, socioeconomic outcome, and healthcare utilization were similar for WT survivors compared to sibling controls. Radiation exposure to the lungs/chest increased risks for congestive heart failure, especially in patients receiving cumulative doxorubicin in excess of 250 mg/m^2 in total. Overall, considering cardiac concerns and secondary malignancies (slightly increased), overall mortality was marginally increased in pediatric WT survivors treated in the 1970s and 1980s on longer-term follow-up [104].

Site-specific morbidity is also prevalent in survivors, with radiation associated with increased risk for musculoskeletal development (scoliosis and other), gonadal function including fertility (magnified by gonadal toxic therapies such as cyclophosphamide), lung function (radiation pneumonitis), and cardiac insufficiency [105].

Secondary malignancies, not uncommon in chemotherapy-treated children, have been found in Wilms tumor survivors with an absolute excess risk of 7.6/10,000 persons/year, rates substantially lower than most other pediatric cancer survivor populations [106]. One single institution study demonstrated that some WT survivors have increased neurocognitive challenges including poor memory, attention, and general quality of life, independent of treatment variables [107]. Advances in the management of pediatric renal tumors continue to emphasize maximizing survival for higher risk patients and minimization of late effects in lower risk populations [98].

Renal function of survivors has been explored by a number of groups. The SIOP group reported that survivors of non-syndromic unilateral WT have a slightly increased rate of chronic kidney disease after two decades [108]. A report from the St Jude Lifetime Cohort Study reported that no survivor of non-syndromic unilateral WT had an estimated glomerular filtration rate <60 mL/min/1.73 m^2. Hypertension was somewhat common, however, with 35% of irradiated and 25% of unirradiated survivors impacted, compared with 0% controls [109]. Further investigation demonstrated that patients treated with nephrectomy alone, without chemotherapy or radiotherapy, had less impaired renal function with lower rates of proteinuria (12.5%), GFR <90 (21.3%; all >60 mL/min/1.73 m^2) hypertension (6.7%) compared with chemotherapy and/or radiation-treated patients [110].

Abstract

Pediatric oncology patients are at risk for both acute and chronic kidney injury, not only from the cancer itself, but often related to its treatment. Chemotherapy, radiation, medications, infections, hematopoietic stem cell transplant, and newer therapies like CAR-T cells and immune checkpoint inhibitors are beneficial in treating this at-risk population, but also contribute to the risk of kidney injury. Treatment advances in oncology have markedly improved outcomes, with these advances leading to a greater incidence and prevalence of kidney disease in cancer patients. This chapter addresses major nephrology issues affecting the pediatric cancer patient, focusing on acute and chronic management of kidney dysfunction. Within these realms, specific attention is given to kidney injury due to (1) primary oncologic disease, (2) established and emerging treatments, and (3) hematopoietic stem cell transplant. This chapter provides a foundation for the approach to patients that are within the realm of onconephrology, an evolving and expanding field.

Introduction

Cancer is the second leading cause of death in the pediatric population, with leukemia and brain tumors being the two most common malignancies. Recent treatment advances have led to significant improvements in survival. However, the severity of the underlying malignancy and the use of increasingly aggressive therapeutic regimens can cause organ toxicity with both short-term and long-term consequences. Accordingly, acute kidney injury (AKI) and chronic kidney disease (CKD) can occur in children with cancer and is the result of multiple mechanisms. AKI is estimated to affect approximately half of all pediatric patients with cancer or following hematopoietic stem cell transplantation (HSCT) [1]. AKI and CKD in children with cancer are often multifactorial, with kidney injury from both the disease process itself, as well as the treatments employed to eradicate the disease. This chapter will review the specific causes of AKI and CKD in children with cancer and/or those undergoing HSCT and outline the general approach to the evaluation, prevention, and treatment of kidney disease in this high-risk population. Specific attention will be given to therapy-associated nephrotoxicity (chemotherapy, radiation-induced injury, and newer T cell-based therapies (CAR-T), tumor lysis syndrome (TLS), mechanisms of AKI and CKD in HSCT recipients, and considerations for acute and maintenance renal replacement therapy in children with a history of cancer.

Nephrology Evaluation of the Oncologic Patient

The pediatric patient with cancer may present to the nephrologist at any time during their clinical course. Ideally, those with preexisting kidney disease or prior episodes of acute kidney injury (AKI) are either already known to the Nephrology service, or Nephrology is involved early in their diagnosis and treatment course. Close communication between Oncology and Nephrology is essential to provide a collaborative approach in the evaluation, prevention, and management of kidney disease. A thorough history and physical examination with a particular focus on risk factors for preexisting kidney disease, family history of kidney disease, dialysis, or transplants, and a review of systems elucidating renal and urinary symptoms (edema, dysuria, nocturia, enuresis, and hematuria) should be performed. Also, a review of the patient's oncologic diagnosis, medications, and past and planned treatment courses is essential to understanding risk factors for the development of AKI and/or chronic kidney disease (CKD).

With regard to laboratory studies, a baseline evaluation of glomerular filtration rate (GFR) is standard to determine the risk of AKI and CKD and to accurately dose medications. It should be noted equations that use serum creatinine to estimate GFR (eGFR) may have significant limitations in the pediatric cancer population leading to overestimation of GFR in patients with decreased muscle mass from chronic steroid exposure, suboptimal nutrition, or prolonged hospitalizations leading to deconditioning. Therefore, alternative methods for estimating or formally measuring GFR, independent of muscle mass, have increasingly been used to either replace or supplement creatinine-based eGFR. Serum cystatin C is perhaps the most feasible option for estimating GFR in such situations, and is now widely available in many laboratories either in-house or as a send-out. Cystatin C is a small protein produced by all nucleated cells and is cleared by glomerular filtration and is not significantly affected by changes in muscle mass. Cystatin C has been validated in several populations, and when used in concert with creatinine, helps to provide a more accurate estimation of kidney function [2, 3]. In cases where creatinine and cystatin C give widely discrepant results, it may be necessary to consider formal measurement of GFR using nuclear medicine isotopes or iohexol [4].

Evaluation of the patient's urine, specifically focusing on the degree of hematuria and proteinuria/albuminuria, can provide a baseline from which to compare subsequent studies and estimate the risk of later CKD. Similarly, attention should be paid to the serum electrolytes, especially calcium, magnesium, and phosphate which can be markers of tubular injury from nephrotoxic medications.

In addition to routine electrolytes, uric acid and lactate dehydrogenase (LDH) values can estimate the risk of tumor lysis syndrome (TLS) before starting chemotherapy. After starting therapy or HSCT, the complete blood count (focus on hemoglobin and platelet count), LDH, haptoglobin, and peripheral smear for schistocytes can help to monitor for and diagnose complications from endothelial injury such as thrombotic microangiopathy (TMA).

Hypertension in cancer patients is very common, affecting at least one-third of patients with malignancy or after HSCT [5]. Causes of hypertension include pain, fluid and salt overload, steroids, calcineurin inhibitors, TMA, and tumor infiltration or compression of the kidney or its vasculature. Severe, acute elevations in blood pressure are a risk factor for posterior reversible encephalopathy syndrome (PRES) and seizures [6]. Chronic hypertension can result from prior chemotherapy, radiation, or TMA [7]. Therefore, is it critical to pay close attention to the accurate measurement of blood pressure, both in the outpatient setting and when patients are admitted to the hospital. Auscultatory methods to measure blood pressure are performed both at the onset of care and at each follow-up nephrology visit. Should there be any question of masked hypertension, white-coat hypertension, or difficulty assessing suspected hypertension, the use of 24-hour ambulatory blood pressure monitoring (ABPM) is now recommended as standard of care. Recent studies in both general and pediatric HSCT populations demonstrated the utility of screening APBMs in diagnosing hypertension, masked hypertension, and pre-hypertension [8].

Baseline imaging studies evaluating the kidneys and bladder structure are often helpful in patients with concern for AKI or CKD after cancer diagnosis. Renal ultrasound and more detailed examinations including CT and MRI can assess for tumor involvement of the kidneys or bladder, screen for preexisting congenital anomalies of the kidney or urinary tract, and can detect urinary obstruction or hydronephrosis necessitating urology consultation. Imaging studies such as voiding cystourethrogram (VCUG) or contrast-ultrasonography can be employed when there is concern for voiding dysfunction or obstruction. Chronically, children with a history of cancer may be at higher risk for short- or long-term kidney and bladder abnormalities including transient change in renal size [9], nocturnal enuresis from bladder injury, or renal concentrating defects and renal cysts that require long-term follow-up.

Finally, in certain situations, kidney biopsy can provide helpful information in the diagnosis and management of AKI and CKD in children with cancer. Specific situations where kidney biopsy may be warranted include AKI of unclear etiology, persistent isolated proteinuria or nephrotic syndrome, chronic unexplained decreases in GFR, or when there is concern for TMA or BK polyomavirus (BKPyV) nephropathy, as a renal biopsy in these situations can provide the necessary evidence for an accurate diagnosis [10]. While generally safer than an open biopsy, there are still risks for bleeding with percutaneous biopsy, especially in the cancer patient with thrombocytopenia or uncontrolled hypertension. [11] Therefore, careful planning and consideration is critical in balancing the risks and benefits of biopsies in this patient population.

Acute Kidney Injury

AKI is characterized by an abrupt reduction in GFR, either with or without reductions in urine output, and is a very common complication in cancer patients. A retrospective study demonstrated that greater than 50% of pediatric patients with cancer developed AKI, with an average of nearly two AKI episodes per patient [1]. Similarly, up to 40% of HSCT recipients have also been shown to develop AKI [12], although an individual patient’s risk for AKI after cancer diagnosis or HSCT is highly variable and dependent on relevant co-morbidities, primary cancer diagnosis, and the treatment course. There are many classification systems to define AKI. Currently, most prefer to use the Kidney Disease: Improving Global Outcomes (KDIGO) methodology to define AKI as an increase in serum creatinine over set periods of time and/or reductions in urine output to determine staging of AKI. Other groups have defined AKI using the Pediatric Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease (pRIFLE) system or the AKIN criteria [13]. Additionally, the renal angina index (RAI) incorporates a history of HSCT into its grading system [14]. In this section, we first review the broad categories of AKI (pre-renal, intrinsic, and post-renal) that affect the pediatric cancer population and then focus on specific etiologies pertinent to patients with cancer or HSCT recipients including specific nephrotoxic medications and complications.

AKI Due to Hypoperfusion

Ineffective circulating blood volume leading to AKI can manifest in several ways in the pediatric patient with cancer. Volume depletion or dehydration is commonly caused by nausea, vomiting, diarrhea, or other insensible losses. Anorexia or mucositis can lead to marked reductions in oral intake. Therefore, use of enteral feeding tubes, intravenous fluids, or parenteral nutrition is common in patients with cancer. Even with adequate fluid intake, inadequate effective arterial blood volume can be caused by sepsis, effusions, ascites, and heart failure. Liver dysfunction can lead to sinusoidal obstruction syndrome (SOS, described below) and physiologic derangements consistent with hepatorenal syndrome. Capillary leak syndrome can occur due to sepsis or cellular therapies such as chimeric antigen receptor t-cell therapy (CAR-T). Use and choice of fluid intake should be carefully considered in children with cancer. Attention to the patient's intake, output, fluid balance, and daily weight is essential to prevent fluid overload and need for more intensive management. Even in cases of euvolemia and effective arterial volume, abdominal compartment syndrome from tumor burden can result in inadequate perfusion to the kidneys and use of calcineurin inhibitors can result in afferent arteriole vasoconstriction and reduction in glomerular blood flow.

Intrinsic AKI

The glomerular, tubular, vascular, and interstitial components of the kidney can be commonly injured in children with cancer. TMA is defined as endothelial cell injury with microvasculature and laboratory findings notable for hemolytic anemia with schistocytes and thrombocytopenia in the glomerular and proximal peritubular capillaries leading to reductions in kidney function. TMA is likely due to multiple etiologies, including primary disease, chemotherapy and radiation, and infections. Glomerular injury can also occur with medications. Acute tubular necrosis can be caused by shock, sepsis, and drug toxicity. TLS, cast nephropathy, and drug crystal deposition can all cause tubular obstruction. Additionally, drug-induced tubular dysfunction can lead to significant electrolyte derangements. Lymphoma and leukemia can infiltrate the interstitium. Drug-induced acute interstitial nephritis can be caused by a wide range of medications and immunotherapeutics. From an infectious standpoint, both BKPyV and adenovirus can cause nephropathy in HSCT recipients.

Obstruction-Induced AKI

Obstruction can occur from tumor burden and invasion, retroperitoneal fibrosis secondary to radiation, ureteral stenosis secondary to BKPyV or adenoviral infection, nephrolithiasis, or from blood clots secondary to hemorrhagic cystitis after HSCT. Reduced urine output should be evaluated promptly, examining all causes of AKI, with particular attention to volume status. If adequate volume status is demonstrated, a careful trial of diuretics (e.g., a loop diuretic such as furosemide or bumetanide) may be considered as a "furosemide stress test" to assess the patient's ability to make urine [15]. With persistent oliguria or anuria, further evaluation including imaging (either point-of-care or standard ultrasound), laboratory studies, and consultation with urology should promptly be performed to determine need for further intervention to relieve any identified obstruction.

Medication-Induced AKI

Chemotherapeutics are, by design, meant to cause cell toxicity, and can therefore have significant off-target effects throughout the body. Given the high proportion of cardiac output to the kidneys and their roles in toxin and metabolite clearance, there is a high risk for nephrotoxicity after exposure to medications or their metabolites. Such exposure can result in kidney injury, which can be exacerbated in situations of underlying AKI or CKD [16] (Table 3).

Glomerular Injury from Chemotherapy

Glomerular injury due to chemotherapeutics can result in TMA or disruption of the normal glomerular filtration barrier leading to proteinuria. Cessation of the offending agent is often the best treatment for glomerular injury in these situations, but progression to CKD can occur. Mitomycin is an alkylating agent that has been described to cause significant renal dysfunction by TMA-dependent and TMA-independent mechanisms [17, 18], typically in a dose-dependent manner with doses greater than 70 mg/m^2. Therefore, in treatment regimens requiring its use, efforts are made to limit doses to less than 40 mg/m^2 [19]. Gemcitabine is a pyrimidine antimetabolite that is structurally similar to cytarabine, and both cause proteinuria and nephrotic syndrome, which is reversible with cessation of the medication. Gemcitabine also results in TMA in as many as 2.2% of patients. [20]

Antiangiogenic medications targeting vascular endothelial growth factor (VEGF) signaling pathways are increasingly used in the treatment of malignancies, especially in solid tumors where angiogenesis is essential for tumor growth and establishment of metastases. Bevacizumab is a humanized monoclonal antibody that serves as a potent VEGF inhibitor by binding directly to VEGF. Bevacizumab can cause TMA and has also been shown to lead to hypertension, proteinuria/nephrotic syndrome, focal proliferative cryoglobulinemia, and immune-complex mediated proliferative glomerulonephritis [21, 22]. Other antiangiogenic agents include the multi-target tyrosine kinase inhibitors (mTKIs) sunitinib, sorafenib, and pazopanib. These are small molecule inhibitors targeting downstream kinase pathways of VEGF signaling [23]. Typically, renal injury in mTKIs is demonstrated by proteinuria, hypertension, and nephrotic syndrome, with renal biopsy findings demonstrating minimal change disease or focal segmental glomerulosclerosis (FSGS). TMA is also less commonly seen with this class of medications. Notably, there is a case report of thrombotic thrombocytopenia (TTP) associated with pazopanib use that was successfully treated with pazopanib cessation and plasmapheresis, challenging the classic understanding that TTP is not a drug-induced disease [24]. Progression of renal injury with VEGF inhibitors and mTKIs is usually halted or reversed with cessation of the offending agent, and there is some evidence that concomitant use of renin-angiotensin blockade may improve overall patient survival [25], although long-term studies are needed to better understand their impact on the development of CKD.

Tubular Injury from Chemotherapy

Cyclophosphamide and ifosfamide are alkylating agents that serve to disrupt and inhibit DNA synthesis. They are effective in a wide range of malignancies including solid tumors, lymphoma and leukemia, and are also utilized in conditioning regiments for HSCT. Each of these medications causes distinct injury due to toxic metabolites. Cyclophosphamide is metabolized in the liver to generate acrolein, which is an irritant to the genitourinary tract and results in early onset hemorrhagic cystitis after HSCT. Standard prophylaxis includes hyperhydration and administration of mesna, which directly binds acrolein [16]. Ifosfamide is metabolized to chloracetaldehyde, which results in acute tubular necrosis and development of Fanconi syndrome [26]. Higher doses of ifosfamide are associated with a greater degree of CKD [27].

Methotrexate inhibits dihydrofolate reductase, which results in an inability to effectively perform DNA synthesis and cell replication. Methotrexate is widely used in oncology as both chemotherapy and graft-versus-host-disease (GVHD) prophylaxis after HSCT. Methotrexate is both filtered in the glomerulus and secreted into the tubules, and is poorly soluble in acidic urine due to it being a weak organic acid. Typically, low dose methotrexate does not cause any significant renal injury, but at doses greater than 1 g/m^2 it can lead to tubular crystal nephropathy [28, 29]. The resulting AKI can be either oliguric or non-oliguric, depending on the severity of injury, and the urinalysis is generally bland without proteinuria. The risk of methotrexate crystal nephropathy can be reduced by aggressive hydration and urinary alkalinization. Several drugs, including salicylates, penicillin, NSAIDs, and probenecid, are known to interfere with the tubular secretion of methotrexate and increase the risk of methotrexate nephrotoxicity. Treatment of methotrexate nephropathy includes the use of leucovorin which bypasses dihydrofolate reductase inhibition. In severe cases, glucarpidase (also known as CPDG2), which is a recombinant enzyme of bacterial origin that metabolizes methotrexate into inactive compounds, can be utilized as a rescue from significant methotrexate-induced nephropathy [26]. Due to intracellular methotrexate accumulation and also being highly bound to plasma proteins, hemodialysis and hemoperfusion can provide modest overall reductions in methotrexate, but there is significant rebound of methotrexate levels in the blood, typically requiring multiple sessions to achieve sustained reductions in toxic levels of methotrexate [30, 31].

Cisplatin is a platinum-containing chemotherapeutic that induces production of reactive oxygen species and inhibits antioxidant enzyme activity. Cisplatin induces kidney-specific expression of tumor necrosis factor alpha, resulting in programmed cell death. [32]. Organic cation transporter 2 is responsible for luminal uptake and concentration of cisplatin in the renal tubular cells. There is an acute reduction in renal blood flow and associated toxicity within hours of administration, and this effect is dose dependent. The resulting tubular injury causes sodium, phosphate, and magnesium wasting [26]. Histologically, cisplatin injury is characterized by tubulointerstitial injury with acute tubular necrosis, cyst formation, and interstitial fibrosis [32]. Recovery usually follows cessation of cisplatin administration, but magnesium wasting can persist for longer. Careful dose selection and maintaining hydration are the mainstays of minimizing cisplatin toxicity and magnesium supplementation may provide benefit although this is not well validated [33]. Amifostine can serve as an antioxidant to limit cisplatin's nephrotoxicity, but its use is limited due to cost, side effects, and concern for amifostine reducing cisplatin's antitumor potency. Both carboplatin and oxaliplatin are less nephrotoxic [34, 35].

Finally, immunomodulatory therapies can also lead to tubular injury. Ipilimumab is within the family of checkpoint inhibitors that targets CTLA-4 to reduce inhibition of cytotoxic T cells, thereby potentiating the cytotoxic effects of the native immune systems in treating cancer. Both ipilimumab and nivolumab have been associated with AKI [36], granulomatous allergic interstitial nephritis [37], and a case report of lupus nephritis [38]. With more clinical interest and research focusing immunomodulation and checkpoint inhibitors, both the use of these drugs, and associated kidney injury, may increase with time. Furthermore, cell-based therapies such as CAR-T are a novel and powerful tool to treat refractory cancers, but have been reported to cause AKI [39–41]. In CAR-T cell therapy targeting leukemia, studies have shown significant risk for AKI associated with an inflammatory state called cytokine release syndrome that results in multiorgan dysfunction [42, 43]. As this therapeutic approach is in the relatively earlier stages of use, more data is needed to better understand the mechanisms of kidney injury.

Tumor Burden and Resection

Intraparenchymal renal tumors are relatively uncommon in the pediatric population, with Wilms tumor being the most common pediatric renal tumor. Germline *WT1* mutations are responsible for a variety of associated syndromes such as Wilms tumor-aniridia syndrome (WAGR), Denys-Drash syndrome (DDS), and Frasier syndrome [44], all which have an increased risk for developing Wilms tumor [44]. In contrast to the adult population, pediatric presentation of renal cell carcinoma is much less prevalent [16]. Leukemia, lymphoma, and neuroblastoma can infiltrate renal parenchyma and cause significant direct injury, hypertension, and obstruction [16]. Extrarenal tumors such as bladder rhabdomyosarcomas can also obstruct the urinary tract. For unilateral renal tumors, surgical nephrectomy is the mainstay of treatment. Often, there is adequate preserved renal function with compensatory hypertrophy in the solitary kidney, albeit with reduced renal reserve [45]. Patients are prone to further renal injury and the development of hypertension [46, 47]. However, long-term follow-up studies in patients with Wilms tumor treated with unilateral nephrectomy demonstrate hyperfiltration and FSGS [48], but the overall incidence of end-stage kidney disease (ESKD), as defined by dialysis or renal transplant, is low between 1 and 2% [49]. In contrast, Wilms tumor patients requiring bilateral partial nephrectomies demonstrate a higher risk for ESKD [50, 51].

Radiation-Induced Injury

Radiation therapy is used as either a treatment for certain types of malignancies or as part of the conditioning regimen prior to HSCT. Typically, radiation therapy regimens use focused or total body irradiation (TBI), and conditioning regimens utilize TBI [52]. Radiation to the kidney is associated with

Table 1 Dosing Considerations for Cancer Therapeutics in CKD and ESKD. This table is adapted from Krens et al [93]. There are limited data for many chemotherapeutics in CKD and ESKD, especially in the pediatric population. There are several helpful references that can be used to determine optimal dosing and frequency, although there can be significant variation in the recommendations. These resources (listed at the bottom of this table) can and should be utilized in concert with pharmacists and oncologists, in addition to manufacturer-provided prescribing information (e.g., US-FDA clearinghouse https://dailymed.nlm.nih.gov/dailymed/index.cfm)

Cancer treatment medications requiring dose adjustment consideration in CKD or ESKD

Agent	Recommendations	
Arsenic trioxide	GFR $\geq$30 mL/min: no need for dose adjustment is expected GFR <30 mL/min: consider 50% of the original dose HD: consider 10 mg three times weekly post-dialysis	
Bleomycin	GFR >50 mL/min: no dose adjustment is needed GFR 10–50 mL/min:75% of the original dose GFR <10 mL/min: 50% of the original HD: 50% of the original dose may be considered	
Carboplatin	Renal impairment: dose calculation based on renal function, using Marina/St. Jude's formula (pediatric formula adapted from Calvert's formula) HD: dose according to Marina/St. Jude's formula with GFR equals 0. Perform HD between 12 and 24 h after administration ***Marina/St.Jude's formula:*** *Dose* **(mg/m^2)** = *Target AUC x [(0.93 x corrected GFR normalized to patient's BSA (mL/minute/m^2)) +15]*	
Carmustine	GFR 46–60 mL/min: 80% of the original dose GFR 31–45 mL/min: 75% of the original dose GFR <30 mL/min: not recommended HD: not recommended	
Cisplatin	*Curative* GFR 50–59 mL/min: 75% of the original dose GFR 40–49 mL/min: 50% of the original dose GFR <40 mL/min: not recommended HD: 50% of the original dose may be considered	*Palliative* GFR 50–59 mL/min: 75% of the original dose GFR <50 mL/min: not recommended HD: not recommended, consider carboplatin
Cyclophosphamide	GFR $\geq$30 mL/min: no dose adjustment is needed GFR 10–29 mL/min: consider 75% of the original dose GFR <10 mL/min: not recommended, if unavoidable consider 50% of the original dose HD: not recommended, if unavoidable consider 50% of the original dose	
Cytarabine (high-dose $\geq$ 1 g/m^2) for low-dose, no dose adjustments are needed	GFR $\geq$60 mL/min: no dose adjustment is needed GFR 31–59 mL/min: 50% of the original dose GFR <30 mL/min: not recommended HD: 50% of the original dose, start HD 4–5 h after administration	
Dacarbazine	GFR $\geq$30 mL/min without hepatic impairment: no dose adjustment is needed GFR <30 mL/min: 70% of the original dose may be considered HD: 70% of the original dose may be considered	
Daunorubicin	GFR 30–50 mL/min: 75% of the original dose GFR <30 mL/min: 50% of the original dose HD: 50% of the original dose	
Doxorubicin	GFR >10 mL/min: no dose adjustment is needed GFR <10 mL/min: no need for dose adjustment is expected HD: 75% of the original dose may be considered	
Etoposide (Intravenous)	GFR >50 mL/min: no dose adjustment is needed GFR 10–50 mL/min: 75% of the original dose, increase if tolerated HD: not dialyzed, consider 75% of the original dose	

(continued)

Table 1 (continued)

Fludarabine	GFR >70 mL/min: no dose adjustment is needed GFR 30–70 mL/min: 80% of the original dose GFR <30 mL/min: not recommended HD: 80% of the original dose. Start dialysis 12 h after administration
Gemcitabine	GFR ≥30 mL/min: no dose adjustment is needed GFR <30 mL/min: no need for dose adjustment is expected HD: no need for dose adjustment is expected. Start HD 6–12 h after administration
Hydroxycarbamide (Hydroxyurea)	GFR <60 mL/min: 50% of the original dose HD: 50% of the original dose
Ifosfamide	GFR > 10 mL/min: no dose adjustment is needed GFR <10 mL/min: 75% of the original dose HD: 1,000 mg/m^2 followed by HD 6–8 h later
Imatinib	GFR 40–59 mL/min: no need for dose adjustment is expected GFR 20–39 mL/min: 50% of the original dose, increase if tolerated HD: use with extreme caution
Irinotecan	GFR ≥10 mL/min: no need for dose adjustment is expected GFR <10 mL/min: start with 50–66% of the original dose, increase if tolerated HD: start with 50–66% of the original dose, increase if tolerated
Melphalan	*Conditioning treatment*: Renal impairment/HD: no need for dose adjustment is expected *Palliative treatment* GFR 30–50 mL/min: consider 50% of the dose GFR <30 mL/min or HD: not recommended
Mercaptopurine	GFR ≥30 mL/min: no need for dose adjustment is expected, can consider dosing interval to 48 h GFR <30 mL/min: increase dosing interval to 48 h HD: not recommended
Methotrexate	GFR ≥50 mL/min: no dose adjustment is needed GFR 20–50 mL/min: 50% of the original dose GFR <20 mL/min not recommended. If unavoidable consider hemodialysis HD: not recommended, if unavoidable 50% of the original dose, can be dialyzed with daily high flux dialysis or hemofiltration
Mitomycin	GFR ≥30 mL/min: no need for dose adjustment is expected GFR <30 mL/min or HD: not recommended due to nephrotoxicity
Oxaliplatin	GFR ≥30 mL/min: no dose adjustment is needed GFR <30 mL/min: consider 50% of the original dose HD: consider 50% of the original dose, HD within 1–5 h after administration
Pemetrexed	GFR ≥40 mL/min: no dose adjustment is needed GFR 30–40 mL/min: 80% of the original dose GFR <30 mL/min: not recommended HD: not recommended
Sorafenib	GFR >40 mL/min: no dose adjustment is needed GFR 20–39 mL/min: 200 mg BID, dose-escalation based on tolerability GFR <20 mL/min or HD: 200 mg QD, dose-escalation based on tolerability
Streptozocin	GFR 46–60 mL/min: 50% of original dose GFR 31–45 mL/min: not recommended, if unavoidable consider 25% of the original dose GFR ≤30 mL/min or HD: not recommended

(continued)

Table 1 (continued)

Sunitinib	Renal impairment: no dose adjustment is needed HD: no initial dose adjustment is needed, increase dose based on sunitinib + active metabolite C_{trough} levels:
Thiotepa	GFR $\geq$30 mL/min: no need for dose adjustment is expected GFR <30 mL/min: consider 70% of the original dose, increase if tolerated HD: consider 70% of the original dose, increase if tolerated
Topotecan (Oral and intravenous)	GFR $\geq$40 mL/min: no dose adjustment is needed GFR 20–39 mL/min: 50% of original dose GFR <20 mL/min: not recommended, if unavoidable consider 25% of the original dose HD: not recommended, if unavoidable consider 25% of the original dose

Cancer treatment medications not typically requiring dose adjustment for CKD or ESKD

Asparaginase	Dactinomycin	Gemtuzumab-ozogamicin	Ofatumumab	Tamoxifen
Bevacizumab	Dasatinib	Inotuzumab ozogamicin	Paclitaxel	Temozolomide
Blinatumomab	Docetaxel	Irinotecan	Panitumumab	Trastuzumab
Bortezomib	Everolimus	Mitotane	Pegaspargase	Vinblastine sulfate
Busulfan	Fluorouracil	Nivolumab	Pembrolizumab	Vincristine sulfate

long-term nephrotoxicity [46, 53] causing damage to the glomerulus, tubules, and vascular endothelium [54]. Conflicting data exists regarding the long-term effects of TBI on kidney function, and indeed may be dose-dependent [55] [56, 57], as many of these studies demonstrating delayed renal dysfunction received cumulative prescribed radiation greater than recommended in Children's Oncology Group (COG) guidelines [58].

Tumor Lysis Syndrome

TLS occurs after significant cell lysis of tumor cells and release of their intracellular contents into the bloodstream, leading to hyperkalemia, hyperphosphatemia, hypocalcemia, and hyperuricemia. These electrolyte and metabolite derangements can cause complications in multiple organs including AKI, seizures, and arrhythmias. While TLS can occur spontaneously in patients with Burkitt's lymphoma, it is most commonly encountered shortly after initiation of chemotherapy [52]. Risk factors for TLS include the type of cancer, disease burden at presentation, and the specific treatment regimen. TLS is the most common oncologic emergency with significant risks for morbidity and mortality if not promptly diagnosed and managed (Table 2).

From a pathophysiologic perspective, the rapid increase of released cellular contents into the bloodstream exceeds the normal clearance of the kidney, and the patient with concomitant AKI or CKD is even more susceptible to significant injury. Uric acid, which is a breakdown product of purines, is normally freely filtered in the glomerulus and reabsorption and secretion is regulated by URAT-1 and OAT. With the massive increase of uric acid from highly proliferative tumor cell lysis, there is an accumulation of uric acid crystals within the tubular lumen, which causes direct mechanical injury and obstruction, but has also been demonstrated to cause increased inflammation, increased peritubular capillary pressures, and inhibition of cell repair mechanisms, all of which can contribute to significant AKI. Phosphate, which is a predominantly intracellular electrolyte, is significantly increased in

Table 2 Tumor lysis syndrome definition and risk characterization

A. Cairo-Bishop definition of tumor lysis syndrome (Cairo-Bishop)

Laboratory TLS		**Clinical TLS**
Uric acid	≥8 mg/dL or 25% increase from baseline	Laboratory TLS, **and** ≥1 of the following:
Potassium	≥6 mEq/L or 25% increase from baseline	Creatinine ≥1.5×ULN (for >12 yo)*
Phosphorus	≥6.5 mg/dL (children), ≥4.5 mg/dL (adults), or 25% increase from baseline	Cardiac arrhythmia or sudden death
Calcium	≥25% decrease from baseline	Seizure

*Classic definition limits evaluation in CKD patients and patients <12 yo. Recommend using appropriate definitions for AKI when original schema is inadequate

B. Risk characterization of tumor lysis syndrome

First, determine disease risk by cancer type and relevant characteristics, Then assess relevant modifying factors to determine risk category for recommendations on TLS prophylaxis

Disease risk	**Type of tumor**	**Modifying factors**
Low risk disease	Solid tumors (excluding bulky tumors such as neuroblastoma and germ-cell tumors)	For LRD leukemia and lymphoma in patients with renal dysfunction or renal involvement, consider as intermediate risk for developing TLS
	Myeloma	
	CML	
	CLL treated only with alkylating agents	
	AML w/WBC, <25 × 10^9 and LDH, <2×ULN	
	Lymphoma, except as below	
Intermediate risk disease	Bulky solid tumors (e.g., neuroblastoma and germ-cell tumors)	For IRD in patients with renal dysfunction or renal involvement, consider as high risk for developing TLS
	CLL treated with targeted or biological therapies	
	AML w/WBC, <25 × 10^9/L and LDH, >2×ULN	
	AML w/ WBC 25–100 × 0^9/L	
	ALL w/ WBC <100 × 10^9/L and LDH, <2×ULN	
	Burkitt or lymphoblastic, early stage with LDH<2×ULNL	For IRD in patients with uric acid, phosphate, or potassium above normal limits, consider as high risk for developing TLS
	Lymphoma, Anaplastic large-cell, Stage III/IV, LDH, <2×ULN	
	Lymphoma, Stage III/IV	
	ATL, diffuse large B-cell, peripheral T-cell, mantle cell (blastoid variants)	
High risk disease	AML with WBC>100 × 10^9/L	
	ALL with WBC>100 × 10^9/L	
	ALL with LDH>2×ULNL	
	Lymphoma, advanced stage with LDH>2×ULNL	
	Burkitt or lymphoblastic lymphoma, early stage, with LDH>2×ULNL	

(continued)

Table 2 (continued)

B. Risk characterization of tumor lysis syndrome		
	Burkitt or lymphoblastic lymphoma, advanced stage	
Prophylaxis recommendations based on TLS risk		
Low risk	**Intermediate risk**	**High risk**
Intravenous fluids	Intravenous fluids	Intravenous fluids
Allopurinol	Allopurinol or rasburicase	Rasburicase
Monitoring	Inpatient monitoring	Cardiac monitoring
Daily laboratory tests	Laboratory tests 2–3×/day	Laboratory tests 3–4×/day

Table providing Cairo-Bishop diagnostic criteria for tumor lysis syndrome, as well as summary of relevant pediatric cancer risk characterization and recommended prophylaxis for prevention of tumor lysis syndrome. For more complete risk characterization, including adult and more rare cancers, please refer to Cairo et al. 2010 [61]

the bloodstream with tumor lysis. Hyperphosphatemia leads to phosphate avidly binding to calcium, resulting in hypocalcemia that can cause acute cardiovascular and neuromuscular complications, as well as calcium-phosphate precipitation and deposition in tissue, including the kidney. Hyperkalemia also is common with TLS and can result in significant morbidity and mortality.

Several scoring systems have been proposed to help define and stratify the risk of TLS [59, 60]. The modified Cairo-Bishop definition uses specific changes in electrolytes as laboratory markers of TLS, and the presence of arrhythmias, sudden death, seizures, or a >1.5 times increase in serum creatinine above the upper limit of normal to define TLS. These criteria assume adequate hydration status, and derangements are not due to medications, and prophylaxis with a hypouricemic agent. Further work stratifies the risk of severity for specific presentations of cancer, to allow for prognosis and decision making in management [61], (Table 2). Limitations of the scoring system include that AKI is only defined for adolescents and older children and using 1.5 times the upper limit of normal serum creatinine may underestimate risk in those with CKD or decreased muscle mass.

Management of TLS begins with prophylactic strategies. Nephrotoxic medications should be avoided as possible, and regular labs should be obtained to monitor progression of TLS. Volume expansion and rates of intravenous fluid administration that promote brisk urine output ensure adequate renal perfusion and promote excretion of uric acid, potassium, and phosphate. Alkalinization of the urine does improve the solubility of uric acid, but at the same time promotes precipitation of calcium-phosphate crystals, and therefore is not recommended. Administration of allopurinol or febuxostat, xanthine oxidase inhibitors, help to prevent purine conversion of uric acid, and given their mechanism of action, are more effective as prophylactic rather than treatment measures. Notable differences between allopurinol and febuxostat are that febuxostat does not have the same concerns for hypersensitivity as allopurinol; it is metabolized by the liver, rather than the kidney; it does not need dose adjustments for a reduced GFR; and it has fewer drug interactions with chemotherapy than allopurinol. For treatment of hyperuricemia rasburicase is used, which is a fungal-derived uricase oxidase enzyme that works by converting uric acid to allantoin and is much more soluble than uric acid, thereby decreasing hyperuricemia. Rasburicase can also be used prophylactically in high-risk situations and does not require altered dosing for diminished GFR. The patient's G6PD status should be evaluated prior to use, since rasburicase use in patients with G6PD deficiency can cause methemoglobinemia and hemolysis. It should also be noted that rasburicase's activity persists in blood after collection, so samples should be processed promptly or placed on ice to ensure accurate results. Use of the above preventive measures has greatly reduced the need for renal replacement therapy in TLS patients. Should these more conservative

Table 3 Chemotherapy-induced renal dysfunction

A. Common chemotherapy-induced nephrotoxicity	
Chemotherapeutics with glomerular toxicity	
Agent	**Injury**
Gemcitabine	TMA, hypertension, AKI
Mitomycin	TMA, AKI, hypertension (dose-dependent)
Bevacizumab	TMA, proteinuria/nephrotic syndrome, hypertension
VEGFR mTKI (Sunitinib, Sorafenib, Pazopanib, Nivolumab)	TMA, minimal change disease, (collapsing) FSGS, AKI
Chemotherapeutics with tubular toxicity	
Agent	**Injury**
Cisplatin	ATN AKI, Chronic interstitial fibrosis
Ifosfamide	ATN, Fanconi syndrome
Methotrexate	Crystal nephropathy, nonoliguric AKI
Pemetrexed	ATN AKI AIN, Tubular atrophy and interstitial fibrosis
Ipilimumab	AIN
Chemotherapeutics with genitourinary toxicity	
Agent	**Injury**
Cyclophosphamide	Hemorrhagic cystitis
B. Common chemotherapy-induced electrolyte abnormalities	
Electrolyte abnormality	**Common causative agent**
Hyponatremia	Cisplatin, cyclophosphamide, ifosfamide, methotrexate, pemetrexed, interferons, vincristine, vinblastine
Hypokalemia	Cisplatin, glucocorticoids, ifosfamide
Hypomagnesemia	Cisplatin, calcineurin inhibitors, ifosfamide, EGFR inhibitors (cetuximab and panitumumab)
Hypophosphatemia	Cisplatin, Ifosfamide, and imatinib

Table providing commonly used chemotherapeutics and associated toxicities. (Adapted from Glezerman et al [22]), and electrolyte abnormalities associated with common chemotherapeutic agents

measures prove inadequate and the patient is demonstrating life-threatening symptoms or lab values, the use of either hemodialysis (HD) or continuous renal replacement therapy (CRRT) with high clearance rates is warranted [62], with the risk of interdialytic rebound of serum electrolytes less likely with CRRT.

AKI Associated with HSCT

Sinusoidal Obstruction Syndrome

SOS is another common complication of HSCT associated with AKI. The hepatic sinusoidal endothelial injury that occurs causes significant liver dysfunction and portal hypertension, with resultant systemic hypotension, AKI, and an increased risk for multiorgan dysfunction and mortality. Previously described as veno-occlusive disease (VOD) of the liver, SOS has become the preferred nomenclature, due to a better understanding of the specific hepatic sinusoidal cell injury that occurs. SOS is very common in pediatric HSCT recipients, with estimates of prevalence ranging between 20% and 30%. In children with SOS, severe disease involving multiorgan dysfunction is as high as 30–60%, a rate higher than that seen in the adult population. SOS appears similar to hepatorenal syndrome, with volume overload, ascites, jaundice, and hepatomegaly. Due to portal hypertension, there is systemic hypertension, hyponatremia, and evidence of renal dysfunction (Table 4).

There are multiple risk factors for SOS including age <1-year, preexisting liver dysfunction, prior transplant, prior radiation treatment, and conditioning including busulfan (with or without cyclophosphamide) and fludarabine. Generally, the more intensive the conditioning regimen and the less well-matched the transplant, the higher risk of SOS. SOS typically presents within 30 days of transplant but in the pediatric population it can occur at any time after transplantation. There had classically been two major classification schemata utilized for the diagnosis of SOS, the modified Seattle [63, 64] and the Baltimore [65] criteria, both focusing on hepatomegaly, weight gain, and hyperbilirubinemia in the first three weeks following HSCT. Review of these two classification systems in pediatric cancer patients suggested that they may be too restrictive for accurately diagnosing pediatric SOS [66], with

Table 4 Schemata for diagnosis of sinusoidal obstruction syndrome (SOS)

	Baltimore Criteria	**Modified Seattle Criteria**	**EBMT Criteria-Pediatric**
Timing:	Within 21 days of transplantation	Within 20 days of transplantation	No time limitation after transplantation
Findings:	Serum bilirubin ≥ 2 mg/dL, **AND ≥2 of the following findings**	**≥2 of the following findings**	**≥2 of the following findings**
	Hepatomegaly	Hepatomegaly	Hepatomegaly (best if confirmed by imaging) above baseline
	Weight gain >5% above baseline	Unexplained weight gain > 2% from baseline	Unexplained weight gain on 3 consecutive days, despite the use of diuretics, **OR** a weight gain >5% above baseline
	Ascites	Bilirubin serum level > 2mg/dL	Ascites (best if confirmed by imaging) above baseline
		Right upper quadrant pain	Rising bilirubin from a baseline value on 3 consecutive days, **OR** bilirubin ≥ 2 mg/dL within 72 h
			Unexplained consumptive and transfusion-refractory thrombocytopenia

Table providing sinusoidal obstruction syndrome (SOS) criteria from the Baltimore [65], modified Seattle [63], and the European Society for Bone Marrow Transplantation (EBMT) [67] guidelines. Other causes that could explain these findings should be excluded prior to diagnosis. The EBMT recommendations provide specific diagnostic and severity criteria for both the pediatric and adult population, and the adult criteria are available in the EBMT references provided

diagnosis limited by the short post-transplant time cutoff and absolute lab values more appropriate for adult patients. To address these limitations, the European Society for Bone Marrow Transplantation (EBMT) recently developed distinct adult and pediatric diagnostic criteria, [67], and all three SOS classification schemata listed for comparison in Table 4. When suspected, additional laboratory testing in SOS commonly demonstrates elevated transaminases, hyperbilirubinemia, elevated coagulation parameters, and hypoalbuminemia. Up to one-third of all pediatric SOS patients do not present with hyperbilirubinemia and this is often a finding later in the progression of disease, so normal bilirubin levels do not rule out SOS. Although only part of the EBMT criteria for diagnosis, thrombocytopenia that does not improve with platelet transfusions is often observed early in the disease course, and this refractory thrombocytopenia can precede other diagnostic criteria by a week [68]. There have been attempts to find alternative biomarkers for endothelial injury in SOS including PAI-1, thrombomodulin, VWF, soluble ICAM-1, ATIII, and VCAM. Liver biopsy can be used to definitively diagnose SOS, but the diagnosis is largely a clinical diagnosis, and in the context of clinical presentation, labs, and imaging findings, a diagnosis can be made without risking the complications of a liver biopsy.

With the concern for significant morbidity and mortality in SOS, careful monitoring, prophylaxis, and prompt treatment is essential to minimize risk of progression to multiorgan dysfunction and death. Ursodiol is utilized as a prophylactic treatment for SOS, with demonstration of improvement in mortality with its use. Fluid management of SOS remains challenging due to the portal hypertension and resultant systemic hypotension. Adequate systemic intravascular volume needs to be maintained to ensure adequate organ perfusion and can be achieved with resuscitative and maintenance intravenous fluid, but care and attention should also be taken to avoid volume overload in these patients.

Defibrotide, a preparation of oligo-deoxyribonucleotides derived from porcine intestine, is the only medication currently approved for the treatment of SOS and has been shown to provide a survival benefit. The precise mechanisms of action for defibrotide remain to be elucidated, but it demonstrates significant anti-inflammatory and anti-thrombotic effects. Defibrotide is not renally cleared and as such does not require renal dosing for impairments in renal function. Studies in Europe have also demonstrated that prophylactic use of defibrotide has provided benefit in reducing the rate of SOS, but additional studies are still ongoing, and its use is not widely employed as a preventative intervention.

Thrombotic Microangiopathy

There are multiple causes for TMA in children with cancer including chemotherapy, medications, hypertension, and secondary to HSCT. TMA is most commonly diagnosed after HSCT and is associated with higher post-transplant mortality as severe cases can be associated with multisystem organ dysfunction involving the lungs, gastrointestinal tract, and central nervous system [69]. TMA presenting after HSCT may be caused by radiation, or specific agents such as VEGF inhibitors (bevacizumab) and antimetabolites (gemcitabine), as described above [26]. Calcineurin inhibitors in conjunction with sirolimus may also increase the risk of TMA after HSCT [70, 71]. Other risk factors include acute GVHD, infection, and type of transplant [69, 72], and there has been evidence that TMA severity is worsened by complement pathway mutations present in either the recipient, or the HSCT itself [73, 74]. TMA is a microvascular disease than can lead to activation and recruitment of inflammatory cells and activation of coagulation and complement pathways [72]. The resulting damage to the kidney can lead to hypertension, AKI, and proteinuria [26]. Further clinical indicators of TMA include thrombocytopenia or increased platelet transfusion requirements, anemia or increased red cell transfusion requirements, elevated LDH, low haptoglobin, and schistocytosis. Notably, hypertension may be an early clinical indicator of TMA, with a common characteristic of the patient requiring additional antihypertensive agents beyond that expected for the current clinical course, with the requirement for three antihypertensives greatly raising the concern for TMA [69]. TMA most commonly presents at 5–7 weeks following HSCT with most cases presenting before day 100. TMA in autologous recipients occurs even earlier, with a median of 18 days following HSCT [75]. Renal biopsy in TMA demonstrates thrombi within glomeruli and small arterioles, mesangiolysis, and proliferative or sclerotic lesions [76]. Increased LDH and proteinuria have also been shown to be early markers for TMA, while changes in serum creatinine require significant renal injury [69]. Thrombotic thrombocytopenic purpura, a TMA typically due to antibody-mediated inhibition of ADAMTS13, is uncommon but reported in the HSCT literature and should be ruled out by ADAMTS13 testing, if clinically suspected [77]. While CNI withdrawal can be considered if no other cause is found, it is essential that a careful evaluation for infection, GVHD, or other etiology should be performed first. Other immunosuppressive approaches include transition to steroids or mycophenolate as alternative immunosuppressive agents, prompt use of plasma exchange, rituximab, and eculizumab [72], although to date no randomized clinical trials have been conducted with these interventions in the treatment of TMA after HSCT.

Graft-Versus-Host Disease

GVHD occurs with allogeneic HSCT and is characterized by injury to native host tissue, particularly epithelial damage from immune responses from the allograft, and mediated by donor T-cell and cytokine effects. Acute GVHD primarily targets the skin, liver, and gastrointestinal tract and is a risk factor for AKI. Acute and chronic GVHD may also involve the kidney, either through direct T cell-mediated injury or chronic systemic inflammation leading to renal endothelial and tubular damage [72]. Kidney biopsies performed in patients with acute GVHD classically demonstrate tubulitis and peritubular capillaritis, as well as complement deposition and pathologic findings of TMA [76]. Elafin, a marker of skin GVHD, has also been studied in HSCT patients with kidney injury, and higher levels of elafin and associated with persistent albuminuria and progression to CKD [78]. A diagnostic clue for evaluating risk of GVHD is review of the chimerism of the donor T cells. If there is mixed chimerism, it suggests tolerance and reduced risk of GVHD, while full donor T-cell chimerism may indicate that tolerance has been broken and the patient is at risk for GVHD [79]. Progression of disease to chronic GVHD can be associated with significant glomerular injury and development of minimal change disease and membranous nephropathy on histology. Kidney biopsy may provide diagnostic guidance when considering GVHD, as changes in immunosuppression regimens need to be carefully considered in these patients.

Proteinuria and Nephrotic Syndrome

Proteinuria is common among the cancer and HSCT population, with reports of proteinuria being observed in more than a third of HSCT patients with AKI [80]. Proteinuria has also been demonstrated to be helpful in assessing the prognosis of TMA in HSCT patients [69], and albuminuria at 100 days following HSCT is associated with significantly greater risks of CKD and non-relapse mortality [81].

Nephrotic syndrome can present after HSCT and typically occurs >100 days after transplant. Nephrotic syndrome can occur with or without AKI, and there appears to be a greater risk for those who had developed GVHD, and nephrotic syndrome typically presents with reductions in intensity of immunosuppression [72]. Biopsy results demonstrate mainly membranous nephropathy or minimal change disease, but membranoproliferative glomerulonephritis, FSGS, and IgA nephropathy have also been reported. Given the wide range of etiologies observed, the use of a renal biopsy should be considered in HSCT recipients with nephrotic range proteinuria to help guide immunosuppressive treatment, especially if renal findings are associated with acute or chronic GVHD [26]. Rituxumab has also demonstrated efficacy in treatment for membranous-associated nephrotic syndrome [82].

Dialysis in AKI

Studies have suggested that approximately 1–2% of all patients with cancer, and up to 5–10% of pediatric HSCT recipients will require acute RRT [41, 83, 84, 85]. Mortality in children with cancer requiring CRRT has been reported to be greater than 50% [86], and the 1 year mortality rate for HSCT recipients requiring RRT is nearly triple those not requiring dialysis (85% vs. 29%) [84]. The indications for RRT in children with cancer are the same as those in the general population, including refractory volume overload, refractory metabolic acidosis and electrolyte disturbances, symptomatic uremia, and intoxication with dialyzable medications. Despite this overlap in the indications for dialysis, patients with cancer are disproportionately more likely to require RRT owing to the severity of their disease and complications from therapies, which is evidenced by the tripling of the likelihood of mortality in CRRT patients, when they have a diagnosis of cancer [87].

The choice of acute RRT modality is determined primarily by the patient's presentation and level of acuity but is also influenced by physician and institution preferences. Typically, the choices include intermittent HD, CRRT, and peritoneal dialysis (PD). All three modalities have unique benefits and challenges. In the critically ill patient, the high blood flow rate and significant fluid shifts that occur during HD limit its use, favoring the use of CRRT and PD in the ICU. Given the rapid availability of central venous access in the intensive care setting, CRRT is commonly used in resource-rich settings, but PD has also been used as a mode of RRT in the critically ill patient, and with careful management, dialysis can be initiated nearly immediately after PD catheter placement. One major benefit of CRRT is the ability to continuously control relative contributions of dialytic and convective clearance, while providing the ability to titrate ultrafiltration by the bedside nurse to achieve the degree of volume removal necessary to optimally support the patient [88]. This slow and sustained fluid removal in hemodynamically unstable patents makes it the often-preferred modality of RRT in the intensive care setting when all three modalities are available. The intermittent filling and emptying typical with PD makes it a slightly less preferred modality, but PD's utility in critically ill patients has been repeatedly demonstrated [89], and is a reasonable RRT modality when vascular access limitations do not allow for central venous access. For clinically stable patients, HD provides a rapid and efficient means to provide RRT over several hours and therefore allows patients to participate in rehabilitation, therapy, education, play, or other developmentally appropriate activities.

Drug Dosing in CKD and ESKD

Accurate dosing of medications, especially chemotherapy, is critical in patients with AKI and requires close collaboration with inpatient pharmacy teams. Table 1 provides recommendations regarding dosing in CKD and ESKD for more common oncologic medications, but it is beyond the scope of this chapter to provide specific guidance for all medications in cancer patients with reduced kidney function. However, there are several considerations that help to best approach balancing effective treatment with minimizing drug toxicity and harmful side effects. Of principal importance is shared management with oncology, nephrology, and pharmacy. Review of the available literature can be used to determine optimal dosing for patients on CRRT, and the specific expertise of pharmacists is particularly useful, especially given that dosing decisions need to be made based on limited available evidence. Common strategies include dose adjustments, less frequent dosing intervals, and allowing laboratory data such as drug levels, markers of renal and hepatic function, and, as in the case of marrow suppression, blood cell counts [90]. Additionally, there are guidelines for many medications that provide thresholds for reducing the dose of or holding medications, which often are guided by eGFR. With regard specifically to dosing while on dialysis, specific guidelines exist for many chemotherapies, with guidelines for timing and frequency of administration relative to dialysis [91, 92] [93].

Electrolyte and Volume Disturbances

Hyponatremia

Hyponatremia is the most common electrolyte disturbance observed in cancer patients and has been demonstrated to have negative correlations with outcomes [94]. There are multiple causes for hyponatremia including paraneoplastic syndromes resulting in antidiuretic hormone (ADH) production, side effects from chemotherapeutic and adjunctive medications, concomitant medical conditions, and iatrogenic causes including total parenteral nutrition and intravenous fluid administration [94]. Although more common in the adult population, paraproteinemia can be a cause of pseudohyponatremia, that should be considered in the appropriate clinical context. Multiple chemotherapeutics can directly cause hyponatremia via syndrome of inappropriate diuretic hormone release (SIADH), including cyclophosphamide, platinum alkylating agents, methotrexate, interferons, vincristine, vinblastine, and ifosfamide. Cyclophosphamide and cisplatin also cause hyponatremia by increasing tubular ADH efficacy and/or direct tubular injury preventing sodium reabsorption [95]. Hyponatremia can also be induced as a side effects of chemotherapeutics, including nausea, vomiting, cardiac toxicity from doxorubicin and other anthracyclines, and endocrine disruption from immunotherapeutics. Mass lesions from brain cancer can also result in sodium derangements. Medications associated with the management of cancer complications are also responsible for hyponatremia, with SIADH being the etiology for opioid, antidepressant, antipsychotic, and antiepileptic-mediated hyponatremia, and increased ADH efficacy in the nephron as the cause for NSAID and antiepileptics-mediated hyponatremia [96]. As with all management of perturbations of dysnatremia and ADH signaling, evaluation of volume status, weight, and urine and plasma osmolality are essential in determining the optimal course of treatment, which includes careful fluid administration, fluid restriction when necessary, and consideration of vaptans and demeclocycline. The chronicity of hyponatremia should be assessed, and in accordance with guidelines for any patient with sodium derangements, excessively rapid correction should be avoided.

Hyperkalemia

The common causes of hyperkalemia in any patient also apply to patients with cancer. Additionally, evaluation of cell lytic processes such as rhabdomyolysis, TLS, metabolic acidosis, underlying or drug induced diabetes, and medications should be performed. With the prevalence of leukocytosis and thrombocytosis in select populations, excessive lysis of cells within the laboratory sample tube after collection should be assessed to exclude pseudohyperkalemia. Given the risk and incidence of AKI and CKD in cancer patients, careful assessment of potassium intake, through nutrition, supplementation, and medications, should be closely monitored, to avoid iatrogenic hyperkalemia. Hyperkalemia secondary to TLS is a common complication encountered during the initial presentation (as discussed above).

Hypokalemia

Hypokalemia can be due to inadequate intake or excessive losses. Excessive potassium losses commonly occur through diarrhea and vomiting, and also other sources such as gastrointestinal fistulae or cutaneous losses. Medications commonly used in children with cancer can also cause potassium losses through dysregulation of normal tubular handing handling and include amphotericin, cisplatin, ifosfamide, and glucocorticoids. While potassium derangements are typically limited to the time during medication use, significant numbers of pediatric patients treated with ifosfamide have demonstrated persistent hypokalemia long after completion of treatment. Uncommon causes of hypokalemia directly attributable to tumors include neuroendocrine neoplasms that can promote secretory diarrhea, ACTH-secreting tumors, and tumors that secrete either cortisol or aldosterone and through stimulation of mineralocorticoid receptors are able to induce aldosteronism and associated hypokalemia. Furthermore, acute myelogenous leukemia has been reported to result in direct renal tubular damage, with a putative mechanism attributed to lysozyme secretion from cancer cells [97]. Treatment for hypokalemia in these situations is typically with potassium supplementation.

Hypomagnesemia

There are several causes of hypomagnesemia in pediatric cancer patients, including poor oral intake, inadequate supplementation in parenteral nutrition, and excessive losses through diarrhea. Cisplatin is a common cause of drug-induced hypomagnesemia and can be improved with supplementation, but often appears to persist for years or longer after completion of treatment. Patients on calcineurin inhibitors typically need magnesium replacement as well. Rarely used in pediatric cancers, epidermal growth factor receptor inhibitors such as cetuximab and panitumumab prevent insertion of TRPM6 into the distal tubular apical lumen, which results in renal wasting of magnesium and can be diagnosed by measuring the fractional excretion of magnesium in urine. Unlike cisplatin, EGFR inhibitor-mediated hypomagnesemia improves following cessation of treatment.

Hypercalcemia

Hypercalcemia can occur by multiple different mechanisms in the cancer patients. One common cause is increased lysis of tumor cells either from high tumor burden or initiation of chemotherapy. Another mechanism is hypercalcemia of malignancy believed to be due to stimulation of osteoclasts via direct or indirect tumor cell activation. This is much less common in pediatric cancer than adult cancer; however, it can cause significant hypercalcemia. The spectrum of this presentation is quite broad, ranging from mild and asymptomatic to severe sequelae including coma and arrhythmia. Treatment focuses on enhancing urinary excretion of calcium and limiting the ongoing calcium liberation from bone. Aggressive hydration promotes calcium excretion from the kidneys, with the use of diuretics demonstrating additional benefit. Limiting osteoclast activity through the use of bisphosphonates has been employed with some benefit, although they have been demonstrated to cause renal tubular injury, FSGS, and reports of renal failure in pediatric patients [98]. The RANKL inhibitor denosumab has also been used as a treatment for significant hypercalcemia of malignancy [99]; however, there can be severe and refractory rebound hypercalcemia beyond discontinuation of denosumab, so extreme caution is warranted.

Hyperphosphatemia and Hypophosphatemia

Hyperphosphatemia is most commonly associated with TLS and exogenous administration of phosphate-containing fluids and medicine, especially in patients with reduced kidney function (due to AKI and/or CKD) also increases the risk for hyperphosphatemia. Appropriate volume expansion and limiting additional phosphate burden are the mainstays for management. Hypophosphatemia is seen in cancer patients undergoing chemotherapy and is typically due to a combination of poor oral intake due to cancer and associated treatments, as well as renal phosphate wasting from chemotherapeutic agents. Ifosfamide, cisplatin, and imatinib have all been demonstrated to cause phosphate wasting through Fanconi syndrome. Typical treatment is with phosphate supplementation, and this should be done with care in patients with decreased kidney function due to the risk of hyperphosphatemia.

Volume Status

Both hypovolemia and hypervolemia are significant concerns in cancer patients. Close monitoring of fluid intake and output is essential, as are accurate vital signs and daily weights, to monitor volume status. Anorexia, inadequate fluid intake, increased insensible and other fluid losses, diuretic use, sepsis, and third spacing are common causes for hypovolemia in cancer patients. These can occur simultaneously and place the kidney at risk for AKI and hypoperfusion. Conversely, fluid overload is common in the pediatric cancer population, and has been demonstrated to have severe negative outcomes, with modeling suggesting a 3% increase in mortality for each 1% of fluid overload, and patients with greater than 20% fluid overload are eight times more likely to die than patients with less than 20% fluid overload [87]. For pediatric oncology patients requiring acute dialysis treatment, fluid overload was a more sensitive predictor of need for RRT than creatinine or urine output [86, 100]. Therefore, careful evaluation of volume status, and prompt initiation of RRT, when indicated, may prevent excessive fluid overload and its associated increases in mortality.

Infection

Patients with cancer have a much greater risk of infection than that of the general population, with a relative risk of infection approaching 10 when compared to the general population [101]. There are multiple reasons for this increased risk, including tumor-induced immune dysfunction, chemotherapy and/or radiation-induced immune dysfunction, as well as disruption to innate immunity (including barrier function) due to medications, treatments, or invasive medical devices and instrumentation [102].

Fever in the neutropenic patient is a common inpatient and outpatient oncologic complication that can rapidly progress to critical illness if not promptly evaluated and treated. Underscoring the risk with fever in neutropenia, the mortality rate 50 years ago was greater than 90%, but with refinements in chemotherapy, more intensive evaluation and standardization of empiric treatment, that mortality rate has dropped to less than 1% [103], underscoring the necessity for a thorough work-up, as bacteria, fungi, and viruses can all cause significant illness. Typically the most common etiology for fever is bacteremia, but a prospective study showed that urinary tract infections can be as frequent a cause for fever in the neutropenic patient, underscoring the utility of urinalysis and careful evaluation for UTI [104]. In the cancer patient, the causative organisms for UTI do not differ significantly from those of the non-oncologic patient, and there is little data assessing the frequency of pyelonephritis relative to the general population – although there is additional concern for fungal pyelonephritis in the cancer population [102].

Given the concerns regarding significant immunosuppression and risk of complication with direct catheterization, the current recommendations recommend collection of a clean-catch or midstream (rather than direct catheterization) urine sample for culture (not relying on urinalysis for screening). Due to the risk of significant illness or death, urine collection should not delay antibiotic treatment [105]. Given the high rate of infection, prompt empiric treatment with antibiotics is utilized to prevent septic shock, which can have significant morbidity, including renal hypoperfusion and resultant AKI. Prophylaxis and treatment of such infections can include nephrotoxic antimicrobials, most notably vancomycin, aminoglycoside, amphotericin, foscarnet, acyclovir, and cidofovir. Careful monitoring of drug levels and collaboration with pharmacy is critical to optimize dosing, maximizing antimicrobial efficacy while limiting toxicity. When possible and based on the local epidemiology, alternative agents can be selected to decrease the risk of nephrotoxic AKI.

There are a wide variety of viral infections that cause morbidity in cancer patients, with several having a particular affinity of the kidney and genitourinary tract. BKPyV has minimal effect on the general immunocompetent population but has been demonstrated to cause reactivation and pathologic changes with immunosuppressive requirements from transplantation. The most common pathologic finding of BKPyV infection is hemorrhagic cystitis, with 18.7% of a HSCT cohort developing hemorrhagic cystitis, with 90% of them demonstrating evidence of BKPyV infection [106]. In addition, BKPyV can cause nephropathy, with renal biopsy evaluation demonstrating positive staining for virus, cytopathic changes in renal tubules, and interstitial nephritis [107].

BKPyV virus also infects the epithelial cells of the urinary tract and can cause ureteral and urethral stricture. BKPyV can be screened for by its presence in the urine, but this alone is not associated with development of nephropathy, so additional urine findings, including decoy cells and/or BKPyV aggregates known as “Haufen” (German for heap or pile), and evaluation of BKPyV viremia provide more diagnostic certainty [108]. Treatment of symptomatic BKPyV is typically reduction of immunosuppression (when possible) in a stepwise manner until remission is achieved, with antivirals such as cidofivir having some benefit, but effectiveness limited by their nephrotoxicity and other side effects. Hemorrhagic cystitis due to BKPyV is treated with hydration, bladder irrigation, pain control, and transfusions, as necessary [106].

Adenoviral infection is also associated with AKI and nephritis in the HSCT population, especially those with significant GVHD [109, 110]. EBV infection is implicated in a wide range of cancers, including Burkitt’s lymphoma and is largely responsible for the majority of post-transplant lymphoproliferative disorder seen following kidney transplantation, and is discussed in the Transplant Considerations section below.

Chronic Kidney Disease

Advances in oncology are leading to continual improvements in survival from the underlying cancer diagnosis. However, with increased survival, there is also increased risk for chronic sequelae following successful treatment, including a risk for CKD. Multiple studies have demonstrated a high risk for progression to CKD in critically ill cancer and HSCT patients [86, 111], with risk factors for progression to CKD including acute renal failure, total body irradiation, GVHD, long-term cyclosporine use, nephrectomy, cisplatin, carboplatin, ifosfamide, methotrexate, and abdominal radiotherapy [112, 46]. Data from the Childhood Cancer Survivor Study has shown an increase in the cumulative incidence of maintenance dialysis 15 years after enrollment from 0.5% in the 1970s to 0.9% in the 1990s [113], and a retrospective cohort study demonstrated a significantly elevated risk for end stage kidney disease (ESKD) for individuals with a history of childhood cancer when compared to the general population (hazard ratio 3.2; 95% confidence interval 1.3–7.7) [114]. The incidence of needing maintenance dialysis following HSCT is likely higher, estimated at 1–2% in several cohort studies of adult HSCT patients [57, 115, 116]. In one study, ESKD was 16 times more likely in patients following HSCT compared to the general population [116]. On the other side, the incidence of previous cancer among dialysis patients is understudied and analyses combining cancer and dialysis registries are needed. In a study of 74 French adults initiating dialysis with a previous diagnosis of cancer, survival at 1 and 2 years was similar compared to non-cancer dialysis patients matched for age and sex [117]. In a collaborative international study of >900,000 patients, approximately 5% of dialysis patients either had a previous diagnosis of cancer or primary renal disease caused by cancer or amyloidosis [118].

Growth

It is extremely common for patients with CKD, either pre-dialysis or on dialysis to demonstrate significant delay in linear growth, with the requirement for supplemental growth hormone. However, there have been concerns regarding the use of growth hormone in cancer patients and cancer survivors, based on reports of secondary neoplasms in patients using recombinant growth hormone. In a cohort of 172 pediatric cancer survivors, there was an increased incidence of secondary neoplasms [119]. While a rigorous study has yet to conclusively assess the relative risk of growth administration in cancer survivors, careful consideration and collaboration with the patient's oncologist, and potentially endocrinology, are warranted on case-by-case basis.

Nutrition

Nutritional considerations remain important in the management of patients with CKD to ensure adequate protein intake for growth and development. It is recommended that established expert guidelines are employed as a baseline for nutritional support, and adjusted as needed for the individual patient. Given anorexia, nausea, vomiting, and other limitations in achieving adequate enteral nutrition, consideration of tube feeds or parenteral nutrition may be necessary, as well as volume considerations in the oliguric or anuric patient.

Bone and Mineral Disease

Cancer and its associated treatments can cause impairment of peak bone mass, leading to lower bone mineral density, bone quality impairment, and avascular bone disease [120, 121]. With CKD progression to stages III–V, there is increased risk of renal osteodystrophy and associated derangements of phosphate and calcium handling, leading to hyperparathyroidism and significant bone disease. This is typically managed by vitamin D analogs, phosphate binders, and in more severe cases, calcimimetics and parathyroidectomy. Recently, the role of FGF23 and Klotho has been demonstrated in phosphate metabolism. Targeted FGF23 inhibition through medications such as burosumab is utilized in patients with X-linked hypophosphatemic rickets and was FDA-approved in 2020 for tumor-induced osteomalacia. No human studies have evaluated the use of burosumab in CKD patients, but animal studies demonstrated improvements in several parameters of hyperparathyroidism, but also significantly increased mortality [122], likely due to increased hyperphosphatemia. Therefore, use of burosumab in pediatric cancer patients should be very carefully considered, especially for those with demonstrated or likely reduced kidney function. Otherwise, given the lack of data in this population, following professional society guidelines for management of mineral-bone disease is warranted.

Anemia

Due to the kidney's role in generating erythropoietin, an essential hormone for the development of mature red blood cells, patients with advanced CKD and ESKD invariably develop significant anemia, which is effectively managed with the use of erythropoiesis-stimulating agents (ESAs) such as epogen and darbepoetin. Iron levels and stores are closely monitored, and supplemental iron is provided as needed. The use of ESAs in oncology patients requires careful consideration [123], especially given higher risk of thromboembolic events with ESA use in adults. Meta-analyses of ESA use in cancer patients demonstrated increased mortality both during active chemotherapy and beyond [124]. Proposed mechanisms of ESAs in promoting cancer have been improved oxygen delivery to tumor beds or off-target anti-apoptotic effects [123]. Despite laboratory evidence suggesting a supportive role in ESAs in tumorigenesis and tumor progression, a systemic review was not able to demonstrate that the use of ESA had an effect on tumor response [125].

Typically the recommendations for ESA use is limited in cancer patients, except when hemoglobin levels are below 10 g/dL [126] [127]. A few studies exist in the pediatric population and ESA use has demonstrated modest benefit in reducing transfusion dependence with chemotherapy-associated anemia, and is considered second-line to blood transfusions for managing chemotherapy-associated anemia in the pediatric population [128–130, 131]. There exist multiple recommendations for ESA usage in CKD patients who have completed their chemotherapy, but appear to suggest avoiding ESA treatment in patients with hemoglobin greater than 10 g/dL [132]. There is no clear data to guide when it is reasonable to use ESA in patients in remission.

Maintenance Dialysis

The choice of maintenance dialysis modality to treat ESKD in patients with a history of cancer requires multiple considerations. However, there is no absolute indication for initiation of a specific modality of dialysis. In a cohort of pediatric Wilms tumor patients with CKD requiring RRT, 56% started hemodialysis and 41% started peritoneal dialysis [133]. Many barriers for peritoneal dialysis initiation in adults, including age-related limitations and lack of family support [134], are often not as applicable in younger pediatric cancer survivors, but there remains a need for significant training and support from multiple caregivers in the household, which can sometimes be a limiting factor. Fastidious care of peritoneal catheters is essential, as bacterial peritonitis is a serious complication that can cause major complications, and fungal peritonitis requires catheter removal for definitive clearance of fungal infection. In addition to peritonitis concerns, careful technique must be used to avoid exit site and tunneled line infections. Also, peritoneal membrane failure due to previous abdominal surgery, intraabdominal infection, or irradiation may make peritoneal dialysis challenging or not possible, leaving hemodialysis, either in-center or at home, as the only reasonable option for long-term dialysis [135].

Regarding hemodialysis, achieving adequate blood flow rates requires stable central venous access, most commonly with a central venous catheter, which is often tunneled for greater stability and ease of care. For patients of appropriate size and adequate vascular anatomy, this tunneled line can be used while an arteriovenous (AV) fistula is generated and allowed to mature. In patients with active cancer, careful consideration of AV fistula should be considered, as there is no data in the pediatric population, and scant data among adult cancer patients that suggests a greater degree of early AV fistula failure, largely due to cancer mortality [136]. In all ESKD patients, but especially cancer patients, careful choice of location of vascular access should be considered, even from the onset of treatment, as patients with ESKD will have lifetime needs for central vascular access due to limited allograft survival and these sites should be preserved as much as possible. Brachial access, especially on the non-dominant arm, should be preserved for future AV fistula placement, and complications from iliac central line placement can complicate future allograft anastomoses and suitability for renal transplantation. Therefore, careful attention to peripheral and central venous access in patients with CKD after a diagnosis of cancer is imperative, often requiring close discussion with nephrology, surgery, and interventional radiology.

Kidney Transplantation

For patients with ESKD, dialysis is viewed as a bridge to transplantation, as pediatric kidney transplantation has superior outcomes for survival and quality of life [137]. In addition to the standard kidney transplant listing considerations, there are additional considerations in the oncologic patient, including diagnosis and staging of cancer, risk of recurrence, and duration of remission. Kidney transplant in survivors of childhood cancer is low, with one long-term study showing an incidence of 0.54% for receiving or being listed for a kidney transplant, but accounted for nearly half of all solid organ transplants in this population [138]. There are conflicting data regarding mortality in solid organ transplant patients with a prior history of malignancy in adult and inadequate studies to date in children, but a recent pediatric study demonstrated similar graft and patient survival rates for patients with or without prior malignancy [139].

Although the reported incidence of post-malignancy kidney transplant is low, both advances in cancer treatment regimens and the incorporation of new therapeutics with associated nephrotoxicities mean that the number of cancer survivors with ESKD requiring transplant will continue to increase over time. Apart from providing an impetus to minimize AKI during early cancer diagnosis and treatment, this increasing prevalence highlights the dilemma in determining optimal timing for transplantation. Traditionally, there has been concern about listing an ESKD patient shortly after cure or remission due to perceived risks of malignancy recurrence or short-term cancer mortality, with 2–5 years being the standard interval between remission and listing for an organ transplant, based on data demonstrated that more than half of cancer recurrences happened within 2 years of transplant, and 87% of recurrences within 5 years [140]. Despite this practice, there are several considerations that argue for a shorter time to kidney transplant [141]. The clear survival, morbidity, and QOL benefits should not be underestimated, especially in the developing pediatric patient. Also a comparison of long (>10 years) and short (0–2 years) intervals between cancer remission and kidney transplantation, there was no significant difference in all-cause mortality demonstrated, and this was observed in both all cancer and high-risk malignancies [142]. Furthermore, in a study of Wilms tumor patients, those with more aggressive disease requiring bilateral nephrectomy demonstrated markedly worse morbidity and mortality than more indolent Wilms tumor. However, those differences were ameliorated for those who received transplants early, with demonstration of excellent graft survival in patients with transplants performed as early 6 months following remission [133]. Intriguingly, a study demonstrated that infection-related and malignancy-related mortality was higher in dialysis patients than transplant patients, although this effect was blunted when excluding malignancy as the inciting cause for renal failure [143]. Therefore, a thoughtful evaluation of the risk of recurrence balanced against the benefits of transplantation is recommended in optimizing renal function with long-term survival.

Conclusion

Survival has dramatically improved for children treated for cancer or those undergoing a HSCT, but AKI and CKD remain common in this high-risk population, leading to morbidity and potential increases in non-relapse mortality. Close collaboration between nephrologists, oncologists, pharmacists, dieticians, endocrinologists, transplant providers, intensivists, and infectious disease experts is critical to maximize outcomes for these complicated patients. Careful attention to blood pressure, urine assessments for albuminuria/proteinuria, and kidney function with both serum creatinine and cystatin C is important in the long-term to screen for and manage CKD. As more patients are surviving longer, multi-disciplinary survivorship clinics are increasingly following those treated for cancer or having received a HSCT. Our understanding of the mechanisms of kidney injury has allowed the field of onconephrology to grow, and continued research in this area will hopefully further improve outcomes for patients in the future.

Abstract

Hypertension (HTN) is a significant global health issue. It is the major risk factor for atherosclerosis, leading to the development of cardiovascular disease (CVD) as well as a risk factor for the progression to kidney failure. HTN has its antecedents during childhood, and atherosclerosis is already present in adolescents. This chapter overviews the many pathophysiologic alterations that can lead to the development of HTN. Primary and secondary HTN, the etiology of HTN along with normative values of blood pressure (BP), and the definition of HTN are also reviewed.

Keywords

Cardiovascular disease · Primary hypertension · Secondary hypertension · Target organ damage · Normative values · Ambulatory blood pressure · Pathophysiology · Epidemiology · Home blood pressure · White coat hypertension · Masked hypertension

Introduction

The goal of the first half is to provide the reader with an overview of the many pathophysiologic alterations that can lead to HTN. The latter half is devoted to address issues related to the epidemiology of HTN in children.

Mechanisms of Blood Pressure Regulation

BP is a function of cardiac output and systemic vascular resistance, and much has been learned about the many ways in which these two arms of the equation can be affected, down to the cellular level.

Cardiac Output and Systemic Vascular Resistance

HTN is fundamentally a hemodynamic disorder indicating a disturbance in cardiac output (CO) and/or systemic vascular resistance (SVR). CO is the product of stroke volume (SV), which is determined by preload, contractility, and afterload, and heart rate (HR), which is regulated by the sympathetic nervous system (SNS) and the cardiac autonomic pacemaker. SVR is the resistance to blood flow from systemic vasculature except for the pulmonary vasculature and is sometimes referred to as total peripheral resistance.

Although in adult patients primary HTN is usually associated with elevated SVR, pediatric primary HTN often results from increased HR and/or SV producing increased CO, as a consequence of excessive sympathetic activity. Li et al. reported that cardiac over-reactivity characterized by increased HR, left ventricular ejection velocity, and proximal pulse wave velocity may be the main cause of primary HTN in children [1]. Some of these findings may be gender specific, as the ENIGMA cohort showed that hypertensive males had elevated HR, SV, and CO, whereas hypertensive females had increased peripheral vascular resistance and pulse wave velocity (a measure of arterial stiffness) [2]. Patients with mild HTN have significantly higher CO, cardiac index (CI, a function of CO and body surface area), and sympathetic nerve burst frequency than age-matched controls. In borderline HTN, CI and HR are elevated and calculated SVR is normal, but in progressive HTN SVR increases and CO falls, indicating reduced vascular compliance. However, it is clear that not all hypertensive patients start out with increased CO. In some patients, HTN may develop because of increased SVR. In addition, some patients may develop HTN because of primary renal disease or a genetic defect that increases circulating blood volume through sodium retention.

Changes in Systemic Vascular Resistance and Vascular Walls

Previously, SVR was not thought to differ between normotensive and hypertensive adolescents and young adults. However, the recent Avon Longitudinal Study of Parents and Children (ALSPAC) showed that higher BP was associated with higher CO and higher SVR in a population of adolescents [3]. The ENIGMA cohort [4] showed that SVR was positively correlated with BP in overweight/obese young adults with hypertension, whereas CO was associated with SBP in lean young adults.

Because resistance to flow increases steeply with decreasing blood vessel diameter, SVR is mainly a function of small, peripheral arterioles, whose medial muscle layer thickens in response to sustained HTN. In experimental animals, after the onset of HTN, the earliest structural change observed in the arterioles is thickening of the media due to matrix deposition, smooth muscle cell hypertrophy (increase in cell size without division), and hyperplasia (increase in cell number). The medial smooth muscle cells then rearrange themselves to create a smaller lumen without change in cell number or size, a process termed remodeling. Finally, there may be resorption and loss of blood vessels in the periphery, or “rarefaction,” which has been described in both early and later stages of HTN. In larger vessels, the content of elastin and collagen in the media increases and the number of smooth muscle cells decreases (via medial atrophy, necrosis, or apoptosis), leading to a loss of elasticity and increased vessel “stiffness.” In summary, the hypertensive vessel wall is generally characterized by increased medial thickness or an increased media/lumen ratio of the resistance arterioles, resulting in greater resistance.

Altered vascular structure in HTN is accompanied by functional changes in the cellular components of the vessel wall, altering the balance of vasoconstrictive and vasodilatory mechanisms. Decreased relaxation has been attributed primarily to endothelial dysfunction leading to impaired production of vasodilatory substances including nitric oxide (NO) and prostacyclin. Increased contraction may also result from enhanced smooth muscle cell vasoreactivity, sensitivity to vasoconstrictors, and/or production of vasoconstricting substances such as endothelin and platelet-derived growth factor (PDGF). Smooth muscle cell responsiveness to vasoconstrictors can increase because of greater numbers of receptors or augmented contractile machinery. Moreover, vasoconstrictors frequently stimulate smooth muscle cell growth, and conversely, many growth factors have vasoconstrictor activity (e.g., PDGF is a vasoconstrictor, and angiotensin II is a potent smooth muscle cell growth factor).

Sympathetic Nervous System and Central Nervous System

The SNS plays a major role in BP regulation. Sympathetic output is physiologically regulated by baroreflexes and chemoreflexes to maintain BP, carbon dioxide, and oxygen tension. Sympathetic tone can be altered by a variety of factors including baroreflex dysfunction, obesity, salt intake, systemic inflammation, and psychological stress. Increased SNS activity leads to vasoconstriction and sodium retention. SNS activation is found in early stages of HTN and in uncontrolled severe HTN, and it promotes target organ damage such as left ventricular hypertrophy and increases cardiovascular risk. SNS activation is discussed in detail in the following section on primary HTN.

The renal sympathetic nerves innervate renal vessels, tubules, and the juxtaglomerular apparatus, and renal sympathetic nerve activity (RSNA) influences renal hemodynamics, solute and water handling, and hormone release. Increased RSNA is found in animal models of HTN and in hypertensive humans and acts to constrict the renal vasculature and decrease glomerular filtration rate (GFR) and renal blood flow. The hypertensive response to chronic renal adrenergic activation is associated with sustained increases in plasma renin activity and plasma angiotensin II (Ang II). Sympathetic nerve activation and circulating Ang II appear to have a cooperative effect, as experimental renal denervation in animals decreased the effects of Ang II on proximal tubule chloride and water reabsorption by 75%. A likely mechanism of this interaction is that, in addition to its direct effects on tubular cells, Ang II increases norepinephrine release from renal sympathetic nerve terminals. In experimental renal sympathetic nerve stimulation, Ang II enhanced the renal venous outflow of norepinephrine, an effect that was blocked by an Ang II receptor antagonist. These findings show that Ang II and RSNA work in concert to regulate solute and water handling by renal tubular epithelial cells.

A variety of interventional procedures targeted to the SNS have been tested for their effects on BP. Bilateral renal nerve ablation and carotid baroreceptor stimulation have been investigated as treatments for resistant HTN. Although renal denervation prevents or alleviates HTN in virtually all animal models, the renal denervation in patients with uncontrolled HTN (SYMPLICITY-HTN 3 trial) failed to demonstrate an effect on BP [5]. However, carotid baroreceptor stimulation reduced BP significantly in patients with resistant HTN.

Other potential antihypertensive treatments that modulate SNS function are renalase and catestatin. Renalase is a flavin adenine dinucleotide–dependent amine oxidase that is mainly secreted by the kidney and degrades circulating catecholamines (primarily epinephrine). Catestatin is a chromogranin A–derived peptide that blocks nicotine-stimulated catecholamine release. Both renalase and catestatin modulate cardiac function and systemic BP [6].

BP. The role of the RAAS in pediatric HTN and chronic kidney disease was recently reviewed [7]. Renin and its precursor prorenin are produced in the juxtaglomerular cells of the afferent renal arterioles and activate the RAAS. In addition, extrarenal sites of prorenin to renin conversion exist in many tissues. Major stimuli for renin secretion from the juxtaglomerular apparatus include glomerular underperfusion, reduced sodium intake, and SNS activity. In the classical systemic RAAS, circulating renal-derived renin cleaves hepatic-derived angiotensinogen to form angiotensin I (Ang I), which is converted by angiotensin-converting enzyme (ACE) in the lungs to the major active component of the RAAS, Ang II. ACE also degrades bradykinin, a potent vasodilator, into inactive metabolites. ACE exists in plasma, in the interstitium, and intracellularly. Tissue ACE is present in all major organs, including the heart, brain, blood vessels, adrenals, kidney, liver, and reproductive organs, where it augments the effects of circulating components of the RAAS.

The prorenin receptor, which is found on vascular smooth muscle cells, the distal tubule, and other locations [8], binds both prorenin and renin and facilitates the generation of Ang I from angiotensinogen. Free prorenin has no intrinsic enzymatic activity due to the presence of an N-terminal propeptide that obstructs access of angiotensinogen to the active site. However, prorenin bound to the prorenin receptor has enzymatic activity and, in addition, can be cleaved to form renin, increasing Ang I production. Rats overexpressing the prorenin receptor develop HTN, glomerular sclerosis, and proteinuria and have elevated plasma aldosterone concentrations, and polymorphisms of the prorenin receptor have been associated with human HTN.

Ang II is a potent vasoconstrictor of vascular smooth muscle and thus directly increases BP. Systemic vasoconstriction by Ang II reduces medullary flow, which activates sodium-hydrogen exchanger 3 (NHE3) and Na-K-ATPase in proximal tubules, leading to increased sodium reabsorption. Ang II also stimulates aldosterone release from the zona glomerulosa of the adrenal grand, which increases sodium reabsorption by activating the mineralocorticoid receptor and increasing expression of ENaC.

The effects of Ang II are primarily mediated by the type I and type II angiotensin receptors (AT_1R and AT_2R), both members of the G protein–coupled receptor family. AT_1R activation stimulates vasoconstriction and sodium retention, and excessive activation may lead to vascular cell hypertrophy and hyperplasia, reactive oxygen species generation, and inflammatory, thrombotic, and fibrotic processes [8]. These effects of AT_1R overactivation contribute to left ventricular remodeling, alterations in the morphology and mechanical properties of the vasculature, and endothelial dysfunction. Under physiologic conditions, the AT_2R mainly antagonizes AT_1R actions; its cardiovascular effects are generally opposite to those of the AT_1R and may be protective [9]. In the kidney, stimulation of the AT_2R promotes natriuresis through interactions with the renal dopaminergic system.

A membrane-attached homologue of the angiotensin-converting enzyme termed ACE2 hydrolyzes Ang I to angiotensin 1-9 [(Ang-(1-9)] and Ang II to angiotensin 1-7 [Ang-(1-7)] (Fig. 1) [10]. ACE2 is found in the heart, kidneys, testes, lungs, colon, small intestine, and ovaries. Both Ang-(1-9) and Ang-(1-7) are reported to oppose the functions of the classical RAAS. Reduced ACE2 levels are thought to contribute to primary HTN via impaired degradation of Ang II and reduced formation of vasodilator by-products in the renal endothelium [11]. ACE2 has recently received increased attention because it serves as a receptor of SARS-CoV-2 in nasal and oropharyngeal epithelia. Downregulation of ACE2 by SARS-CoV-2 may reduce Ang-(1-7) production while increasing Ang II levels and AT_1R activation, which may contribute to acute lung injury [12].

Ang-(1-7), the major product of ACE2, is present in the circulation and in many tissues, including heart, blood vessels, and kidney. Ang-(1-7) acts via the G protein–coupled receptor Mas (MasR) [13], which is found mainly in the brain, heart, kidneys, and testicles. Ang-(1-7) regulates renal function by acting at glomerular and tubular sites. While Ang II markedly raises efferent glomerular arteriolar resistance without changing afferent arteriolar resistance, Ang-(1-7) vasodilates afferent arterioles and increases renal blood flow [14]. In vitro studies and findings in anesthetized animals have suggested that Ang-(1-7) acts as a natriuretic/diuretic hormone. In humans, there is increasing evidence that Ang-(1-7) may be involved in the development of primary HTN and the progression of chronic kidney disease [7]. The ACE2/Ang-(1-7)/MasR axis may be a target for fetal programming of cardiovascular and renal function, and a deficiency of Ang-(1-7) may contribute to the increased risk of hypertension and chronic kidney disease in premature infants [15]. Another vasodilator peptide, alamandine, is produced by decarboxylation of the N-terminal aspartic acid of Ang-(1-7) to alanine. Alamandine causes endothelium-dependent vasodilation via the Mas-related G protein–coupled receptor (MrgD). It is found in human plasma and is elevated in ESKD patients [16].

Aldosterone

Aldosterone is produced from deoxycorticosterone by the mitochondrial enzyme CYP11B2 (aldosterone synthase) [17]. As discussed later, mutations in the CYP11B2 gene lead to glucocorticoid-remediable aldosteronism, a monogenic cause of HTN. Aldosterone synthase is expressed in the zona glomerulosa of the adrenal glands, aorta, endothelial cells, vascular smooth muscle cells, hypothalamus, hippocampus, amygdala, and cerebellum. Ang II and Ang III induce aldosterone synthesis, and potassium, endothelin, adrenocorticotropic hormone (ACTH), and vasopressin stimulate aldosterone secretion. Inhibitors of aldosterone secretion include atrial natriuretic peptide, somatostatin, and dopamine. Dietary sodium restriction increases aldosterone secretion, which acts to restore plasma volume. Aldosterone binds to intracellular, high-affinity type I mineralocorticoid receptors that are present in the kidney, brain, heart, colon, and vessel walls. Aldosterone receptor activation induces sodium retention and potassium excretion and enhances sympathetic nervous system function by decreasing norepinephrine uptake in the myocardium. Aldosterone signaling can also cause baroreceptor dysfunction [18] and eventually myocardial and vascular fibrosis [19]. The importance of aldosterone in HTN and cardiovascular disease is highlighted by studies demonstrating that the aldosterone receptor antagonists spironolactone and eplerenone improve endothelial dysfunction and resistance artery stiffness, increase NO bioactivity in chronic heart failure and CKD, reduce cardiac fibrosis, and prevent the development of nephrosclerosis and cerebrovascular lesions [17].

Dopamine

Dopamine is an important modulator of systemic BP with direct actions on the heart, arteries, veins, and kidney. Dopamine is synthesized in sympathetic nerve terminals, and also in non-neural tissues (e.g., kidney and gastrointestinal tract). Dopamine modulates renal epithelial sodium transport and gastrointestinal sodium uptake [20], and it can indirectly modulate BP via release of hormones and humoral agents such as aldosterone, catecholamines, endothelin, prolactin, pro-opiomelanocortin, renin, and vasopressin [21]. Dopamine also modulates fluid and sodium intake via appetite centers in the brain and regulates BP by direct action on neuronal cardiovascular control centers. Dopaminergic blockade and decreased function of dopaminergic receptors are both associated with the development of HTN in rats [20]. Five dopamine receptor subtypes have been identified, which can be divided into D_1-like (D_1 and D_5) and D_2-like (D_2, D_3, and D_4) receptors [20]. Stimulation of D_1 and D_5 dopamine receptors, which are expressed in vascular smooth muscle cells, can cause vasorelaxation, whereas stimulation of D_3 receptors produces either vasodilatation or vasoconstriction, depending on the degree of renal nerve activity. Disruption of the D_3 receptor gene in mice is associated with renin-dependent HTN and a decreased ability to excrete an acute saline load [22]. Fenoldopam, an intravenously administered selective D_1 receptor partial agonist, lowers BP by stimulating peripheral D_1 receptors. Dopamine also activates myocardial β-adrenergic receptors, increasing CO, and plays an important role in modulating vascular smooth muscle tone. At extremely high concentrations, dopamine occupies α_1-adrenergic receptors, producing vasoconstriction.

Dopamine also regulates the expression of other receptors involved in BP regulation (e.g., endothelin-B receptor and AT_1R). Both D_1- and D_2-like receptors downregulate AT_1R expression and function. Aberrant dopaminergic regulation of aldosterone secretion may be involved in the development of some forms of hyperaldosteronism and HTN [21].

Natriuretic Peptides

Natriuretic peptides (NPs) are vasoactive peptides that modulate natriuresis and BP, and also have many other biological activities. At least eight NPs have been described, including atrial natriuretic peptide (ANP), B-type (BNP), C-type (CNP), *Dendroaspis* natriuretic peptide (DNP), urodilatin, uroguanylin, osteocrin, and musclin. Three natriuretic peptide receptors (NPR-A, NPR-B, and NPR-C) have been identified and function as transmembrane guanylyl cyclases, and the related protease convertases (furin, corin, and PCSK6) are known to contribute to NP systems [23].

ANP and BNP have similar biological functions, including potent diuretic, natriuretic, and vasorelaxant effects. In the kidney, they increase GFR by vasodilatation of the afferent arteriole and vasoconstriction of the efferent arteriole, and they promote natriuresis by inhibiting tubular sodium reabsorption and renin and aldosterone biosynthesis. ANP and BNP may reduce sympathetic peripheral vascular tone by blocking vasoconstrictive effects of the RAAS and the SNS. Administration of ANP reduces BP in humans and in animal HTN models by reducing systemic vascular resistance. NPs are cleaved by the zinc-dependent metalloprotease neprilysin, leading to catalytic degradation. The effects of neprilysin on NPs may play an important role in BP control and cardiac function [24].

Endothelin-1

Endothelin-1 (ET-1) is a potent endothelial-derived vasoconstrictive peptide [25]. Three isoforms of endothelin (ET-1, ET-2, ET-3) encoded by separate genes have been identified. ET-1, the most abundant isoform, primarily acts in a paracrine fashion, signaling through ET_A and ET_B receptors. Via the ET_A receptor, ET-1 closes membrane K+ channels, leading to membrane depolarization and smooth muscle cell contraction. In general, activation of the ET_A receptor causes vasoconstriction, whereas the ET_B receptor causes vasodilation and induces production of NO and prostacyclin. The ET_A receptor can also stimulate cell proliferation, while the ET_B receptor prevents apoptosis. In the kidney, ET-1 constricts afferent and efferent glomerular arterioles, reducing renal blood flow and glomerular filtration rate. It also blocks sodium reabsorption by inhibiting tubular Na^+-K^+- ATPase activity in the proximal tubule and collecting duct. ET_B knockout mice have HTN secondary to renal sodium retention, and there is evidence of enhanced vascular ET-1 expression in salt-sensitive hypertensive rat models [26].

Patients with HTN are found to have normal circulating ET-1 levels; however, they have elevated local vascular or renal ET-1 levels. Many ET receptor antagonists have been studied and are found to reduce BP effectively. A recent clinical trial of the ET receptor antagonist aprocitentan in patients with primary HTN showed significant BP reduction [27]. However, although the drug was well tolerated, increased plasma volume and weight gain were noted in patients with a high-sodium diet [28]. Currently, the efficacy of ET receptor antagonists for resistant and refractory HTN is under investigation.

Other Vasoactive Molecules

In addition to the factors described above, many other vasoactive molecules can regulate BP. Because of limited space, the functions of several other vasoactive molecules are summarized in Table 1.

Circadian Rhythm

The circadian rhythm is an intrinsic 24-h cycle that affects numerous physiologic processes. Vascular tone, SVR, heart rate, and BP increase in the early morning hours in both normotensive and hypertensive subjects. These changes correspond to increased plasma renin activity and a surge in catecholamine secretion. BP peaks at approximately 9 a.m. and is lowest at 3 a.m. A significant rise in BP occurs prior to awakening. Diurnal variation of BP has been clearly demonstrated in normotensive children; in hypertensive children, data suggest that diurnal variation is preserved in primary HTN but is abnormal in secondary HTN [29]. Hypertensive patients with blunted BP

Table 1 Other vasoactive agents and their function

Vasoactive molecules	Function
Bradykinin	Vasodilation Increased PGE_2, NO, and natriuresis via bradykinin 2 receptor
Nitric oxide	Endothelium-derived relaxing factor
Prostaglandins	Vasodilation Inhibition of platelet aggregation
Vasopressin	Increased water absorption Arterial vasoconstriction
Urotensin II	Potent vasoconstriction
Adenosine	Vasodilation via A_{2A} and A_{2B} receptors TGF via A_1R, vasoconstriction of afferent arterioles, reduced GFR Vasodilatation and increased medullary blood flow via A_2R
Adrenomedullin	Vasodilation, natriuresis, diuresis, and inhibition of aldosterone production

PGE_2 prostaglandin E_2, *NO* nitric oxide, *TGF* tubuloglomerular feedback, *GFR* glomerular filtration rate

dipping have increased risk of cardiovascular target organ damage and cardiovascular morbidity and mortality [30].

The circadian pacemaker in mammals is located in the suprachiasmatic nucleus (SCN) in the anterior hypothalamus. It receives input about light/dark cycles from the retina via the retinohypothalamic tract, and produces several neuropeptides, including vasopressin and vasoactive intestinal peptide (VIP), which appear to have diurnal peaks of expression and release [31]. Animal experiments have demonstrated that the SCN is linked to multiple sympathetic pathways that affect many components of the cardiovascular system, and it plays a crucial role in synchronizing the peripheral oscillators that are found in all tissues. The primary mediator of SCN action appears to be melatonin, which is secreted by the pineal gland. Melatonin appears to transmit information about light/dark cycles from the SCN to the peripheral oscillators and to other centers in the hypothalamus that regulate cardiovascular activity [32].

Supporting evidence for the role of the SNC and melatonin in BP regulation comes from studies demonstrating that melatonin levels are decreased in hypertensive individuals, and that administration of melatonin lowers BP. Autopsy studies of patients with primary HTN have demonstrated that SCN neuronal populations that produce vasopressin and VIP are reduced, suggesting that in at least some individuals with HTN, normal function of the intrinsic biologic clock is impaired [33]. Melatonin appears to modulate activity of the SNS, has antioxidant activity, and may prevent endothelial dysfunction [34].

The Gut Microbiome

The gut microbiome is recently recognized to be an important neuroimmunological modulator. A systematic review and meta-analysis of the effect of probiotics on BP showed that consumption of probiotics significantly reduced both systolic and diastolic BP [35]. Increased dietary sodium intake may lead to gut dysbiosis, inflammatory cytokine release, and elevated BP. Changes in the gut microbiome may also increase BP via G protein–coupled receptors such as Gpr41, Gper1, and olfactory receptors [36].

Renal Mechanisms

The kidneys respond to changes in arterial pressure by altering the excretion of salt and water; increases in renal perfusion pressure lead to decreases in sodium reabsorption and increases in sodium excretion (pressure natriuresis). The mechanism of pressure natriuresis is related to medullary blood flow, renal interstitial hydrostatic pressure (RIHP), and renal autocoids (NO, prostaglandins, kinins, and Ang II). Increased renal perfusion pressure leads to increases in RIHP, NO, prostaglandin E2, and kinins, and a decrease in Ang II. Increased blood flow to the renal medulla, which normally receives only 5–10% of the total renal blood flow, contributes to washout of the urea gradient. This results in an increase in RIHP, which in turn reduces tubular reabsorption of sodium and water, leading to natriuresis and diuresis, and thereby lowering BP.

Renal autoregulation, or the kidney's intrinsic ability to maintain constant renal blood flow and GFR despite changes in renal perfusion pressure, serves to protect nephron function. However, major variations in renal perfusion can still influence renal excretory function, renin release, and arterial BP. Autoregulation occurs in interlobular arteries, side branches of arcuate arteries, and afferent and efferent arterioles. It depends on myogenic mechanisms present in those vessels, among the most important of which is calcium entry through voltage-gated calcium channels. Tubulo-glomerular feedback also plays an important role in autoregulation. Substantial evidence exists that the primary role of these renal autoregulatory mechanisms is to protect the kidney from damage caused by fluctuations in BP.

Renal autoregulation is reset in animal models of spontaneous HTN. Ang II plays an important role in resetting the autoregulation limits. In the spontaneously hypertensive rat, higher pressures are needed to trigger the vasoconstrictive response in the afferent arteriole, but in the

intermediate portion of the interlobular artery a lower threshold pressure stimulates a greater myogenic response [37]. In the Dahl salt-sensitive hypertensive rat, both the afferent arterioles and the interlobular arteries have reduced myogenic responsiveness to increases in perfusion pressure [38]. Abnormalities in renal autoregulation are more pronounced in patients with severe HTN than in those with moderate HTN [39], suggesting that chronic HTN can induce alterations in renal autoregulation. Thus, disturbed renal autoregulation may contribute to the perpetuation of BP elevation in patients with established HTN.

Finally, the kidney also controls salt and water balance by regulating the number and function of critical sodium transporters and channels. For example, in an animal model of primary HTN, the Dahl salt-sensitive hypertensive rat, Ang II/AVP (arginine vasopressin) receptor dysfunction produces HTN through increased tubular sodium and fluid reabsorption [40]. Expression of many of these proteins is influenced by aldosterone and other hormones that affect BP. As discussed later in this chapter, all monogenic forms of human HTN described thus far can be characterized by alterations in renal ion channels leading to either increased sodium reabsorption or decreased excretion. Thus, the kidney plays a central, complex role in the pathophysiology of HTN.

Primary Hypertension

Primary HTN is a multifactorial disorder in which elevated BP is caused by different combinations of contributing factors described above in different individuals. The following sections will highlight some of the more important mechanisms likely to contribute to the development of primary HTN in children (Fig. 2).

Genetic and Epigenetic Influences

The reason for the cluster of primary HTN within families is partly due to genetic susceptibility. The rare alleles responsible for the monogenic disorders do not associate with primary HTN. Primary HTN is thus considered to be the product of multiple genetic variants interacting with each other. Genome-wide linkage studies using families or siblings reported significant or suggestive linkage for HTN, the results of which were variable. Many association studies (case-control studies) with candidate genes for HTN have been reported, most of which failed to replicate. Genome-wide association studies (GWAS) is an approach that involves rapidly scanning markers across the complete sets of DNA or genomes, of patients and controls to find genetic variations associated with the disease. More than 50 GWAS identified a total of more than 30 common loci associated with primary HTN [41]. While a few novel pathways have been identified which may be related to the pathogenesis of HTN, the clinical utility of GWAS data is at present limited.

Epigenetics is a mechanism that regulates gene expression independently of the sequence of DNA. Evidences are accumulating that epigenetics play an important role in the development of HTN capturing environmental and lifestyle factors [42]. DNA methylation and histone modifications are the two major epigenetic mechanisms. Elevated 11-ß-hydroxysteroid dehydrogenase (11ß-HSD2) promoter methylation was shown to be associated with primary hypertensives with lower activity of 11ß-HSD2. The modulation of the promoter region of WNK4, a regulator of sodium reabsorption, by histone acetylation is another example of epigenetic involvement in the development of salt-sensitive HTN [42]. Agnostic epigenome-wide association studies (EVAS) became also possible, but few related to HTN have been reported [41]. More recently, studies of noncoding RNA that regulate gene expression post-transcriptionally in HTN have been reported [43]. Transcriptomic approach examining RNA expression profile is also being tried. Epigenetic modifications reported in HTN thus far has been summarized recently [44].

Influence of Birth Weight and Perinatal Factors

The findings of Barker et al. relating low birth weight (LBW) to increased risk of death from cardiovascular disease (CVD) in later adult life have led to “developmental origins of health and disease (DOHaD)” concept. An inverse association between BP and birth weight supports the concept although the magnitude is small (−1.5 to −2.0 mmHg/kg). The association was independent of potential confounding factors such as socioeconomic status, maternal and participant smoking, maternal age, and others. Accelerated postnatal growth especially weight gain in LBW individuals was associated with increased BP. A meta-analysis concluded that the inverse linear association primarily exists between birth weight and SBP. Of note, a recent GWAS of birth weight identified 190 loci explaining variance in birth weight and higher adult BP suggesting that the inverse birth weight–BP association is genetic rather than developmental [45].

Most of the initial studies did not make a distinction between LBW as a result of intrauterine growth restriction and prematurity. The role of prematurity per se for the development of HTN was supported by a systematic review and a meta-analysis, which concluded that infants born preterm have modestly higher SBP later in life and may be at increased risk for developing HTN and its sequelae [46]. The effect of prematurity, however, could not be differentiated from that of LBW due to prematurity although not due to intrauterine growth retardation.

Brenner et al. proposed that LBW might be associated with a reduced nephron endowment leading to reduced renal sodium excretion and increased susceptibility to HTN. This hypothesis was supported by studies that showed a relation between birth weight and nephron number. Also, hypertensive white patients have been shown to have significantly fewer glomeruli per kidney than matched normotensives although birth weight was not reported in the study.

Vascular factors (microcirculatory rarefaction, endothelial dysfunction, and arterial stiffness) and hypothalamus-pituitary-adrenal axis are also considered to play a role in the pathogenesis of developmental origins of primary HTN.

Animal studies have supported the epidemiologic evidence. Rat dams fed low-protein diet bear young that are small at birth and later develop HTN. A decreased nephron number was observed in the offspring. Many other DOHaD models have supported various mechanisms of developmental origins of HTN observed in humans.

Other than LBW, maternal smoking, alcohol consumption, obesity, diabetes, and preeclampsia during pregnancy as well as bottle-feeding of newborns have been reported to lead to HTN later in life.

Sympathetic Nervous System Activation

Many evidences suggest that SNS activation/overactivity is the primary mechanism by which BP elevation is initiated in young individuals with primary HTN. Children with primary HTN have resting tachycardia compared to normotensives, and resting heart rate has been found to correlate with BP in epidemiologic studies.

Another manifestation of SNS activation in hypertensive children is heightened cardiovascular reactivity to stress. Hypertensive adolescents had significantly greater increases in heart rate, SBP, and DBP during mental stress than normotensives. Increased cardiovascular reactivity to the cold pressor test predicts the subsequent development of HTN. An interaction between genetic factors and SNS activation is suggested by differences in the cardiovascular response to stress in children with different racial backgrounds or family histories of HTN. Recent evidences suggest a role of several neuropeptides such as neuropeptide Y (NPY), a strong vasoconstrictor, mediating the effects of stresses and sympathetic nerves on BP. A common genetic variation at the human *NPY* locus increases its transcription, systemic vascular resistance, and heritable responses to environmental stress, resulting in elevation of BP [47].

SNS activation in primary HTN is supported by several other evidences. Both children and young adults with primary HTN have elevated plasma norepinephrine levels. Altered heart rate and BP variability as well as hyperkinetic circulation (increased ejection volume) have also been associated with primary HTN in children.

Increased SNS activity has been found in microelectrode recordings from both peripheral and renal sympathetic nerves in hypertensive individuals. There is also substantial evidence to suggest that SNS overactivity may be involved in the development of the vascular hypertrophy, left ventricular dysfunction, and other systemic cardiovascular effects of established HTN. The importance of cardiac component and increased aortic stiffness rather than increased systemic vascular resistance has recently been suggested [1].

Obesity

The prevalence of HTN in obese children is higher. The childhood obesity epidemic appears to be associated with an increase in prevalence of HTN in children. Total body fat mass positively correlates with increased BP. The correlation was stronger for SBP than DBP. In a similar manner to adults, central body fat is more strongly related to BP than peripheral fat in children.

Insulin resistance plays a role in the development of high BP by increasing renal sodium reabsorption (Fig. 3). Increased renal sympathetic nervous activity seems to be responsible for this effect. The second mechanism is through effects on vascular structure and function. While insulin acts as a vasodilator, in hypertensive subjects, this effect is offset by vasoconstriction mediated by increased sympathetic nervous activity. Insulin may also act to stimulate vascular smooth muscle proliferation, leading to vascular medial hypertrophy and increased peripheral vascular resistance.

Leptin, a peptide produced by adipose tissue, is strongly associated with BP. With weight gain, leptin increases to counteract obesity. In obese hypertensives, leptin levels are elevated and correlate with BP [48]. The major link between hyperleptinemia and HTN appears to be increased SNS activity, as demonstrated in animal studies. Leptin also has significant intraglomerular effects, resulting in glomerular sclerosis by increasing TGF-β synthesis. In contrast to leptin, adiponectin inversely correlated with BP in obese adolescents. Unlike other adipocitokines including leptin, adiponectin expression and serum concentration are reduced in obesity.

Activation of the RAAS, oxidative stress, and inflammation are also involved in the mechanisms of obesity HTN, although theses mechanisms and insulin resistance are operative also in nonobese hypertensives. Children with obesity and primary HTN have been demonstrated to have elevated plasma renin activity. In a study conducted in adolescents, urinary levels of F2-isoprostane, a marker of oxidative stress, correlated with body fat and with diastolic BP. Furthermore, immune abnormalities and inflammation have been reported in children with obesity [49].

Fig. 3 Mechanism of hypertension in obesity. SNS, sympathetic nervous system. The figure is created by IY and Dr. Joseph Flynn

Finally, obesity produces direct effects on the kidney that contribute to the development of HTN. The kidneys are compressed by the perirenal fat, which leads to increased interstitial pressure, reduced medullary blood flow, and tubular compression, resulting in increased sodium reabsorption [48].

Dietary Influences

While BP is positively associated with sodium intake in adults, evidence for a direct relation between sodium and BP has been less conclusive in children. A recent systematic review and meta-analysis of experimental and observational studies in children and adolescents concluded that sodium intake is positively correlated with BP [50]. SBP and DBP increase approximately 1 mmHg for the addition of 1 g per day of sodium.

Dietary sodium intake early in life may affect BP in later life. Geleijnse et al. compared infants receiving low or normal sodium-containing infant formula for the first 6 months of life. A significant decrease in BP was found at 6 months and 15 years of age in children fed the lower sodium formula [51].

Potassium supplementation is associated with a decrease in BP in adults. Studies in children, however, gave conflicting results. Longer-term supplementation trials with potassium in hypertensive children induced lower age-related BP increases in SBP and DBP compared with non-supplemented children. A systematic review and meta-analysis found that increasing potassium intake decreased SBP and DBP by 0.28 mmHg and 0.92 mmHg, respectively, in children [52]. In the above-mentioned recent systematic review and meta-analysis, the association between sodium and BP is stronger among children with a low potassium intake suggesting a role to enhance urinary sodium excretion [50].

Uric Acid

Uric acid levels were suggested to be indicators of adolescents at risk for HTN. Subsequently, uric acid was proposed to play a role in primary HTN by contributing to endothelial dysfunction leading to microvascular and inflammatory injury to the kidney. In a short-term prospective study, treatment with allopurinol resulted in reduction of BP in adolescents with newly diagnosed HTN. A follow-up randomized, double-blinded, placebo-controlled trial comparing two mechanisms of uric acid reduction, allopurinol or probenecid, in prehypertensive obese adolescents concluded that uric acid causes increased BP that can be mitigated by uric acid–lowering therapy.

Animal experiment studies suggest that an increase in intracellular uric acid is important for the pathophysiology of primary HTN [53]. Cellular actions of uric acid include inflammation, oxidative stress, immune activation, and release of vasoactive agents. While GWAS did not support the casual association of serum uric acid and HTN, this was considered to be because cellular uric acid is more important for the pathogenesis. Raised BP has been shown to be related to sugar, fructose, and salt in the diet through various mechanisms including uric acid production [54].

Physical Activity and Sleep

There was an inverse dose–response association between levels of recreational physical activity and risk of HTN in adults. In children and adolescents, however, a meta-analysis concluded that short-term exercise does not appear to reduce resting BP. Recent randomized controlled trials assessed the influence of combined lifestyle changes including both diet and exercise on multiple cardiovascular risk factors in overweight adolescents. Although it is difficult to interpret the influence of exercise alone on BP, most studies suggest that physical activity can effectively reduce BP in children. A recent meta-analysis reported that school-based physical activity interventions improved DBP [55]. Physical activity has been shown to be associated with improved vascular structure and function, which is likely to contribute reduction in BP. Sedentary activities are suggested to be more than the opposite of physical activities being associated with SBP after adjustment for confounding factors.

Sleep disorders including sleep apnea are associated with HTN and cardiovascular morbidity in adults. Findings from pediatric studies also suggest that elevated BP is associated with sleep disorders. Several cross-sectional studies have described trends of increasing BP with greater frequency of apnea and hypopnea during sleep in children. In a random sample of the local elementary school children, sleep-disordered breathing was significantly associated with higher levels of SBP. A recent systematic review found an association with sleep (duration, timing, or quality) and HTN in children and adolescents [56].

Breastfeeding

Breastfeeding has been found to be associated with reduced BP in later life, although the findings have not been consistent. Martin et al. conducted a meta-analysis of studies published after 1980 reporting on BP levels in breast- and bottle-fed subjects. Pooled estimates based on a random effects model indicated that breastfeeding was associated with a 1.4 and 0.5 mm Hg reduction in SBP and DBP, respectively. The magnitude of the association is similar to those reported for salt restriction and physical activity. According to a recent systematic review, there is insufficient evidence to draw conclusions about CVD outcomes and infant feeding [57]. There were some evidences that feeding less or no breast milk is not associated with childhood HTN.

The putative association of breastfeeding and lower BP may be explained by a hormonal effect, lower sodium intake, or a protective effect of long-chain polyunsaturated fatty acids that are not present in most formula.

Environment

Adverse childhood socioeconomic status is associated with increased CVD in later life independently of adult socioeconomic status. Children from the low socioeconomic status are reported to have higher BP in adulthood than those from high socioeconomic status although other studies do not support the association. A systematic review and a meta-analysis suggested an inverse association of childhood adverse socioeconomic status and adulthood inflammation, which may possibly explain the association between the former and HTN [58]. Air and noise pollution as well as acute and chronic stress have also been associated with primary HTN in children.

Secondary Hypertension

Major causes of secondary HTN are summerized in Table 2.

Table 2 Differential diagnosis of childhood hypertension

System	Condition
Primary hypertension	
Metabolic syndrome	Dyslipidemia, impaired glucose tolerance, central obesity
Renal	Renovascular disease (syndromic or nonsyndromic) Fibromuscular dysplasia Mid-aortic syndrome Renal artery aneurysm Atherosclerotic renal artery stenosis Transplant renal artery stenosis
	Renal artery or vein occlusion or compression
	CAKUT
	Cystic kidney disease
	Glomerulonephritis Renal infarction
	Monogenic disorders of salt and water handling
Cardiac	Coarctation of the aorta
	Aortic stenosis
Vasculitis	Polyarteritis nodosa
	Takayasu arteritis
	Systemic lupus erythematosus ANCA disease
Endocrine	Thyrotoxicosis
	Cushing syndrome
	Acromegaly
	Hypercalcemia
	Congenital adrenal hyperplasia
	Pheochromocytoma and paraganglioma
	Renin secreting tumor
Neurologic	Intracranial mass
	Intracranial hemorrhage
	Autonomic dysfunction
	Pain
	Anxiety
	Seizures
Respiratory	Chronic lung disease
	Obstructive sleep apnea
Pregnancy-associated	Hypertension exacerbated in pregnancy (Geller syndrome) Eclampsia/Pre-eclampsia Gestational hypertension
Monogenic disorders	Apparent mineralocorticoid excess Congenital adrenal hyperplasia Primary glucocorticoid resistance Liddle's syndrome Pseudohypoaldosteronism type II

(continued)

Mendelian Forms of Hypertension

Molecular genetic studies have identified many gene mutations that affect BP. Below, we will discuss well-characterized monogenic hypertensive disorder [59]. Many of these disorders lead to aberrant distal tubular sodium reabsorption and volume expansion due to hyperaldosteronism, defects in steroid biosynthetic enzymes, and activation of sodium channels or transporters (Fig. 4) [60].

Glucocorticoid-remediable aldosteronism (GRA) or familial hyperaldosteronism type I (FH-I) is an autosomal dominant disease characterized by early onset of HTN with normal or elevated aldosterone levels despite suppressed plasma renin activity. GRA is caused by a chimeric gene that results from unequal crossing-over between the aldosterone synthase (*CYP11B2)* gene and the 11β-hydroxylase gene (CYP11B1) on chromosome 8. Aldosterone synthase is the rate-limiting enzyme for aldosterone biosynthesis in the adrenal glomerulosa, and 11β-hydroxylase is involved in cortisol biosynthesis in the adrenal fasciculata whose expression is regulated by adrenocorticotropic hormone (ACTH). The resulting chimeric gene (*CYP11B1/CYP11B2*) is expressed in the adrenal fasciculata and encodes a protein with aldosterone synthase enzymatic activity whose expression is regulated by ACTH.

Table 2 (continued)

System	Condition
	Hypertension with brachydactyly Mutations in PPAR-gamma
Iatrogenic	Medications
	Salt and water overload
	Umbilical artery catheterization
Illicit drug use	Cocaine, others
Environmental toxins	Cadmium, mercury

CAKUT Congenital abnormalities of the kidney and urinary tract, *PPAR-gamma* Peroxisome proliferator-activated receptor. Table was created by Drs Joseph Flynn and Nicholas Larkins

Consequently, aldosterone synthase activity is ectopically expressed in the adrenal fasciculata under control of ACTH rather than by ANG II or potassium. Aldosterone secretion becomes linked to cortisol secretion, and maintenance of normal cortisol levels results in constitutive aldosterone secretion, which leads to expanded plasma volume and HTN. The expanded plasma volume suppresses secretion of renin, but this fails to diminish aldosterone secretion.

Familial hyperaldosteronism type II (FH-II) is similar to GRA (FH-I), with excess production of mineralocorticoids, but is not suppressed by dexamethasone. FH-II may be associated with a family history of adrenal hyperplasia or adenoma and appears to be more common than FH-I. FH-II is autosomal dominant, and a recent study reported gain-of-function mutations in the *CLCN2* gene, encoding a chloride channel, ClC-2, located at chromosome 3q27 [61].

Familial hyperaldosteronism type III (FH-III) is characterized by massive adrenal hyperplasia with refractory HTN. Patients with the disease were found to have mutations in *KCNJ5* gene encoding the potassium channel Kir3.4 [62]. These mutations alter the ion selectivity of the channel, increasing its conductance to sodium. This results in depolarization of the glomerulosa cells, leading to increased calcium entry and aldosterone production.

Familial hyperaldosteronism type IV (FH-IV) is an autosomal dominant disease caused by gain-of-function mutations in the *CACNA1H* gene, located at chromosome 16p13.3 [63]. *CACNA1H* encodes a T-type calcium channel Cav3.2 localized to the zona glomerulosa. The mutations cause greater influx of calcium ions, stimulating aldosterone synthase.

Hypertension exacerbated in pregnancy (Geller syndrome) results from mutations in the mineralocorticoid receptor. It is an autosomal dominant form of HTN that is markedly accelerated in pregnancy [64]. A systematic screening of patients with early-onset HTN detected a missense mutation in the ligand-binding domain of the mineralocorticoid receptor MR S810L. Carriers of the mutation all developed HTN before age 20, a finding absent among their unaffected relatives. Steroids lacking 21-hydroxyl groups (progesterone, spironolactone) that normally bind but do not activate MR are all potent agonists of the mutant receptor. Because progesterone levels rise 100-fold during pregnancy, all pregnancies among patients harboring this mutation have been complicated by dramatic acceleration of HTN associated with complete suppression of the RAAS.

The syndrome of **apparent mineralocorticoid excess (AME)** is an autosomal recessive condition characterized by early-onset HTN with hypokalemia and metabolic alkalosis, accompanied by suppressed plasma renin activity and the virtual absence of circulating aldosterone. In AME, steroids other than aldosterone activate the mineralocorticoid receptor (MR). Affected patients have a lack-of-function mutation in the gene encoding the renal isoenzyme of 11-hydroxysteroid dehydrogenase (11HSD), resulting in impaired conversion of cortisol to cortisone. Although cortisol activates MR with potency similar to aldosterone, almost all activation of MR is mediated by aldosterone, despite its low plasma concentration. The specificity of MR for aldosterone in vivo is mediated by 11HSD activity, "protecting" the MR from cortisol by metabolizing it to cortisone, which does not activate MR. In AME, the absence of this enzyme allows cortisol to activate the MR, resulting in HTN mediated by increased sodium retention. The 11HSD-2 gene expressed in the principal cells of the cortical collecting duct shows homozygous loss-of-function mutations in AME patients. A systematic review of now 101 patients with the disease has been reported [65].

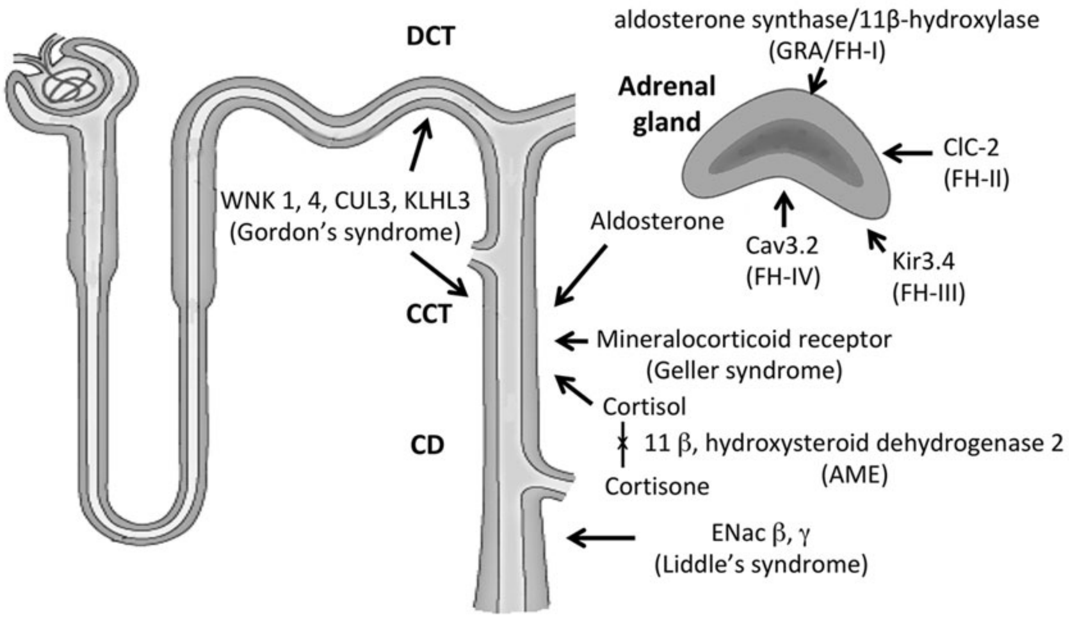

Fig. 4 Single-gene mutation causing hypertension. DCT, distal convoluted tubule; CCT, cortical collecting tubule; CD, collecting duct; GRA, glucocorticoid-remediable aldosteronism; FH, familial hyperaldosteronism; AME, apparent mineralocorticoid excess

Congenital adrenal hyperplasia results from two known defects in either 11-α-hydroxylase or17-α-hydroxylase activity and may cause HTN. These defects lead to overproduction of 21-hydroxylated steroids, which activate mineralocorticoid receptors, resulting in increased sodium reabsorption in distal tubules [60].

Primary glucocorticoid resistance (Chrousos syndrome) is a rare disease representing the partial resistance of the glucocorticoid receptor to glucocorticoids, resulting in excessive ACTH-dependent 11-deoxycortisone and corticosterone production. The disease is caused by a mutation in *NR3C1* gene encoding human glucocorticoid receptor located on chromosome 5q31.3. A cortisol level too high to be controlled by 11β-hydroxysteroid dehydrogenase type II enzyme activity activates mineralocorticoid receptors and increases sodium reabsorption in the distal tubules. Affected individuals have features of mineralocorticoid and androgen excess.

Liddle's syndrome is an autosomal dominant disorder characterized by severe HTN, metabolic alkalosis, and hypokalemia with low renin and aldosterone. Activating mutations in the β or γ subunit of the epithelial Na channel (ENaC), the main sodium channel responsible for sodium reabsorption in the renal collecting ducts, are responsible for constitutively elevated renal sodium reabsorption in Liddle's syndrome. Clearance of the normal channel from the membrane depends upon the sequence PPPXY in the cytoplasmic C termini of the β and γ ENaC subunits. Mutations of this sequence in either subunit prolong the cell surface half-life and increase the number of channels, by reducing channel ubiquitylation and internalization.

Pseudohypoaldosteronism type II, also known as Gordon's syndrome, is an autosomal dominant disorder characterized by HTN, hyperkalemia, hyperchloremic metabolic acidosis, and normal glomerular filtration rate. The WNK1 and WNK4 genes located on human chromosomes 12 and 17, respectively, are responsible for Gordon's syndrome. Two additional genes, CUL3 and KLHL3, located at chromosome 5q31.2 and 2q36.2, respectively, are involved in the proteasomal degradation of WNK proteins, and their mutations are also associated with Gordon's syndrome [66]. Deletions in the first intron of the WNK1 gene increase expression of the gene. This increases sodium reabsorption via ENaC and the Na^+/Cl^- cotransporter (NCC); the latter effect is caused by reducing inhibition of NCC by WNK4. Increased WNK1 expression also decreases potassium excretion by inhibiting the renal outer medullary potassium channel (ROMK). Missense mutations of the WNK4 gene have several effects on renal ion transport. In general, WNK4 inhibits NCC and prevents Na^+ reabsorption in the distal convoluted tubules. The mutated WNK4 does not inhibit NCC, leading to constitutively increased Na^+ reabsorption. WNK4 mutations also inhibit potassium excretion by ROMK, which contributes to hyperkalemia. Studies suggest that WNK1 may also play a role in the pathogenesis of salt-sensitive HTN.

Hypertension with brachydactyly features severe HTN with abnormal skeletal development in the hand and wrist. There are no associated distinguishing biochemical features. This syndrome has been mapped to chromosome 12p12.2 to p11.2 and caused by a mutation in the PDE3A gene encoding a phosphodiesterase [67]. A gain-of-function mutations decrease cellular cAMP levels leading to vascular smooth muscle cells proliferation, luminal narrowing of the vessels, and HTN.

Other Genetic Forms of Hypertension

Mutations in peroxisome proliferator–activated receptor γ (PPARγ) are dominant negative and lead to loss of function. These mutations result in insulin resistance, type II diabetes, and HTN at an early age. Another syndrome of HTN, hypercholesterolemia, and hypomagnesemia shows maternal inheritance of a homoplasmic mutation caused by a cytidine substitution in the mitochondrial tRNA. Mutated tRNA may lead to defective nucleotide modifications, altering structure and function of mitochondria [68].

Hypertension After Renal Transplantation

Readers are referred to Chap. “Renal Transplantation.”

Hypertension in Coarctation of the Aorta

Coarctation of the aorta (CoA) occurs in approximately 1 out of 2500 live births and accounts for 5–10% of all congenital heart disease. CoA-associated HTN has been described in three clinical settings: prior to surgical repair, in the immediate postoperative period following surgical repair, and years after repair. Pre-repair HTN is the result of renal hypoperfusion and activation of the RAAS. There may also be increased SNS activity. In the immediate postsurgical period, paradoxical HTN may be seen, probably resulting from increased activity of the RAAS and SNS. Despite surgical repair of CoA, many patients will later be found to have abnormal BP at rest. Ambulatory BP monitoring (ABPM) usage is recommended to detect HTN in this population. Patients with CoA repair were found to have vascular dysfunction such as reduced arterial response to glycerltrinitrite and impaired flow-mediated dilatation. Carotid intima-media thickness and pulse wave velocity were also significantly increased. These vascular dysfunctions affect BP control and ultimately increase the risk of cardiovascular events. Impaired baroreceptor sensitivity also has been shown to be a key for HTN following CoA repair. These findings suggest that vascular dysfunction may persist regardless of the repair and lead to HTN once the compensation fails. Recoarctation should also be investigated in late post-repair HTN.

Hypertension in Vasculitis

Because of the numerous vessels within the renal parenchyma, the kidneys are frequently targeted by systemic vasculitis. Glomerular inflammation with cellular infiltration, proliferation, and immune complex deposition resulting in nephritis and renal failure has been well characterized in systemic lupus erythematosus (SLE), microscopic polyarteritis, granulomatosis with polyangiitis, IgA vasculitis, and cryoglobulinemic vasculitis. Takayasu's arteritis (TA), an inflammatory process associated with stenosis and obliteration of the aorta and its primary branches, induces HTN by mechanisms similar to those seen in CoA, renovascular HTN, or ischemic kidney disease, as discussed above. Necrotizing vasculitis, such as classic polyarteritis nodosa and Kawasaki's disease, may lead to HTN secondary to thrombosis of inflamed major extrarenal and intrarenal arteries with resulting local (intrarenal) RAAS activation and infarction of the renal parenchyma.

Hypertension in Endocrine Diseases

HTN can occur secondary to many hormonal derangements, including excess production of mineralocorticoids, glucocorticoids, and catecholamines. An excess of growth hormone or parathyroid hormone, hypo- or hyperthyroidism, a renin-secreting tumor, or diabetes mellitus (DM) may also lead to HTN [69].

Pheochromocytomas and paragangliomas are catecholamine-secreting tumors. Pheochromocytomas arise from the adrenal medulla, and paragangliomas arise from extra-adrenal sites, mostly in the head and neck, and also in the thorax, abdomen, pelvis, and bladder. Sustained or paroxysmal HTN is the most common clinical sign of pheochromocytoma, although this may be less common in children. Pheochromocytomas in children have a higher incidence of bilateral adrenal tumors, multiple tumors, and extra-adrenal tumors. The incidence of malignant pheochromocytomas and paragangliomas is higher in children and adolescents.

Although most pheochromocytomas are sporadic, there is a familial predisposition in patients with multiple endocrine neoplasia (MEN) type II, von Hippel–Lindau disease, neurofibromatosis type I, and familial paraganglioma. Rarely, phenochromocytomas/paragangliomas may be found in tuberous sclerosis, Sturge-Weber syndrome, and ataxia-telangietasia. Pheochromocytoma in MEN type II is associated with a germline mutation of the proto-oncogene RET, and pheochromocytoma in von Hippel–Lindau disease results from germline mutation of the *VHL* gene [70]. Familial paraganglioma is an autosomal dominant disorder with catecholamine HTN.

In addition to the genes mentioned above, mutations of succinate dehydrogenase subunit genes (*SDHB, SDHC, SDHD, SDHAF2, and SDHA*), a part of the mitochondrial complex, are found. Mutations of the *TMEM127* gene, which acts as a negative regulator of the mTOR signaling pathway, and mutations of the *MAX* gene, which affects cell proliferation, differentiation, and apoptosis, are associated with pheochromocytomas/paragangliomas.

HTN in pheochromocytoma results from high circulating levels of catecholamines, primarily norepinephrine, epinephrine, and dopamine. Some tumors produce the catecholamine precursor L-dopa. Pheochromocytomas also secrete numerous other peptide hormones, including renin, VIP, neuropeptide Y, somatostatin, and ET-1. These substances are responsible for many of the nonhypertensive symptoms including flushing, sweating, and diarrhea.

Primary hyperaldosteronism (PAL) is now believed to be much more common than previously thought [71]. PAL was first reported by Conn as aldosterone-producing adenoma (APA) and commonly results from adrenal hypertrophy ("idiopathic hyperaldosteronism, IHA"). Rarely, pure aldosterone-producing adrenocortical carcinoma and ectopic aldosterone-secreting tumors cause PAL. GRA, FH-II, FH-III, and FH-IV, which were previously described in this chapter, are also in this category.

APA and IHA both cause excess aldosterone secretion, and both produce HTN with similar clinical features: hypokalemia, renal potassium wasting, suppressed plasma renin activity, and increased plasma and urinary levels of aldosterone. The BP elevation due to aldosterone excess results from an increase in SVR due to aldosterone-mediated increased plasma sodium concentration, which leads to a rise in the intracellular calcium. The increase in intracellular calcium leads to impaired left ventricular diastolic relaxation and enhanced contractility with reduced vascular compliance. Recurrent somatic mutations of the *KCNJ5* gene encoding the potassium channel Kir3.4 may account for 40% of the APA patients, and a germinal *KCNJ5* mutation may be associated with FH-III.

Cushing's syndrome or glucocorticoid excess is caused by exogenous corticosteroids or hypersecretion of corticotropin (ACTH) due to pituitary tumors, ectopic ACTH secretion, or adrenocortical tumors (REFS). There are several mechanisms that contribute to the HTN in Cushing's syndrome [72]. The 11β-HSD2 is overwhelmed in the setting of hypercortisolism, and cortisol binds the mineralocorticoid receptor leading to sodium retention, potassium excretion, and increased blood volume. Hepatic synthesis of angiotensinogen, which stimulates the RAAS, is activated. Upregulation of catecholamine production in the adrenal chromaffin cells and increased peripheral vascular sensitivity to adrenergic agonists may also play a role in the HTN. Furthermore, cortisol affects the vascular system by decreasing vasodilatory elements such as nitric oxide synthase, prostacyclin, prostaglandins, and kallikreins and increasing vasoconstricting ET-1.

Acromegaly or growth hormone (GH) excess. The prevalence of HTN in acromegaly is more than 50% [73]. Excess GH leads to insulin resistance and stimulates smooth muscle cell growth and HTN [73]. Impaired NO production and sodium retention with volume expansion also play a role.

Primary hyperparathyroidism (PHPT). PHPT is strongly correlated with HTN with the prevalence ranging from 47% to 63%. Potential pathogenic mechanisms of HTN in PHPT are elevated intracellular calcium, hypomagnesemia, increased plasma renin activity, and glucose abnormalities. Impairment of endothelial vasodilation by increased intracellular calcium and vasospasm induced by neurohormonal substances due to hypomagnesemia have been reported.

Thyroid disorders. Hypothyroidism as the cause of HTN is often overlooked [74]. Diastolic HTN results from compensatory mechanisms – primarily increased peripheral resistance mediated by increased responsiveness to adrenergic stimulation and increased SNS activity. Also, renin release is decreased and salt sensitivity is increased, leading to increased sodium reabsorption and volume expansion.

Hyperthyroidism, on the other hand, is associated with activation of the RAAS secondary to systemic vascular resistance reduction [69]. Enhanced sodium reabsorption leads to volume expansion. Arterial stiffness is increased despite low systemic vascular resistance leading to a widened pulse pressure. There is also ß2 receptor stimulation, resulting in vasodilatation and increased cardiac output and contractility. The net effect is isolated systolic HTN.

Reninoma. Juxtaglomerular cell tumors of the kidney or ectopic tumors secrete renin and induce HTN associated with hypokalemia, hyponatremia, and other features of RAAS activation. There are approximately 100 reported cases and common in adolescents and young adults [75]. It is also twice as common in women.

Diabetes Mellitus. HTN in patients with type I DM is usually correlated with the development of microalbuminuria and diabetic nephropathy. On the other hand, the majority of patients with type II DM have HTN prior to the development of nephropathy. The pathogenesis of HTN in DM is multifactorial, with hyperinsulinemia, sodium retention, volume expansion, and increased arterial stiffness all playing important roles. Hyperglycemia alters lipid and protein metabolism, and insulin increases SNS activity. DM leads to both microangiopathic and macroangiopathic vascular changes, and autonomous neuropathy causes vascular dysfunction. Numerous studies have shown that endothelial dysfunction in DM may play a significant role in HTN by altering vascular architecture and remodeling in response to hemodynamic changes, low NO and prostacyclin release, increased oxygen-reactive species, and increased ET-1. Insulin may stimulate vascular smooth muscle proliferation and increase peripheral vascular resistance. Hyperglycemia and advanced glycosylation end products may also be important contributing factors.

Hypertension in Pulmonary Diseases (BPD, Sleep Apnea)

HTN in children with chronic lung disease is most commonly seen in infants with bronchopulmonary dysplasia (BPD). An increase in carotid and brachial artery stiffness was associated with a neonatal history of moderate to severe BPD and higher adult diastolic BP [76]. Because the development of HTN is correlated with the severity of lung disease, chronic hypoxia may also be an important mechanism.

Obstructive sleep apnea (OSA), characterized by episodic upper airway obstruction during sleep despite persisting respiratory efforts, leads to intermittent asphyxia, concomitant hypoxia and hypercapnia, and disruption of sleep. As mentioned in primary HTN section above, OSA is a risk factor for HTN. The cycles of hypoxia and hypercapnia result in stimulation of peripheral chemoreceptors and increased sympathetic outflow. Other important contributing factors include endothelial dysfunction, oxidative stress, and inflammation [77]. Because many patients with OSA are obese, coexisting conditions such as metabolic syndrome are probably also involved in the development of HTN.

Hypertension in Neurologic Disorders

Systemic HTN can be seen in a variety of neurologic disorders, including stroke, spinal cord injury, seizures, poliomyelitis, hydrocephalus, head trauma, psuedotumor cerebri (idiopathic intracranial HTN), Guillain-Barre syndrome, and with space-occupying central nervous system lesions (tumor, bleeding, and abscess). Many of these are associated with increased sympathetic outflow, leading to peripheral vasoconstriction and renal sodium retention (see earlier sections). Spinal cord injury, usually above T6, may induce HTN due to aberrant sympathetic activity below the lesion. Widespread SNS activation can be elicited by noxious or non-noxious stimuli, a phenomenon called autonomic dysreflexia. Increased levels of circulating renin and catecholamines have also been reported. In familial dysautonomia, HTN is attributed to central autonomic dysfunction, sympathetic and parasympathetic efferent baroreflex dysfunction, or afferent baroreflex failure.

Increased intracranial pressure (ICP) causes systemic HTN that can be quite labile. ICP is a reversible determinant of efferent sympathetic outflow and the existence of a possible intracranial baroreflex is suggested [78]. Circulating levels of catecholamines may be increased. Hemodynamically, HTN is primarily due to increased SVR. In many instances, especially when ICP is elevated due to trauma, systemic HTN is an important compensatory mechanism for the maintenance of normal cerebral perfusion.

Pregnancy-Induced Hypertension and Preeclampsia

Pregnancy-induced HTN (PIH) may affect up to 8% of all first pregnancies in the USA. PIH includes gestational HTN, preeclampsia, and chronic HTN with superimposed preeclampsia. Preeclampsia is new-onset HTN and new-onset end-organ damage, including proteinuria, after 20 weeks of gestation [79]. The pathophysiology of this complex process involves multiple organ systems. Abnormal cytotrophoblast invasion of spiral arterioles leading to reduced utero-placental perfusion and ischemia appears to be the initiating event. Placental ischemia results in activation/dysfunction of the maternal vascular endothelium, which increases synthesis and release of vasoactive factors such as soluble Fms-like tyrosine kinase-1 (sFlt-1), cytokines, and Ang II type 1 receptor autoantibodies (AT_1-AA).

Increased production of sFlt-1 triggers an imbalance between pro-angiogenic factors (VEGF and PlGF) and anti-angiogenic factor (sFlt-1). This imbalance reduces active angiogenesis, which is necessary for development of the placental vascular network. Another anti-angiogenic protein, soluble endoglin (sEng), may interfere with transforming growth factor β-1 binding to receptors on endothelial cells, which may reduce endothelial NO and vasodilatation. Ischemia of the placenta also increases thromboxane and AT_1-AA, leading to increased production of reactive oxygen species and ET-1, and decreases formation of vasodilators such as NO and prostacyclin. There is also increased synthesis of inflammatory cytokines such as tumor necrosis factor α (TNF-α), interleukin-1 (IL-1), and IL-6, which is activated by TNF-α. Those cytokines, in turn, induce structural and functional alterations in endothelial cells, enhance endothelin production, and reduce acetylcholine-induced vasodilatation.

Another important mechanism may be defective NO production. During normal pregnancy, maternal CO and blood volume increase by 40–50%, whereas SVR and BP tend to decrease. In addition, GFR and renal plasma flow increase by 30–40%. There is substantial evidence that NO plays an important role in mediating those changes. Plasma and urinary levels of cGMP, a marker of NO bioavailability, increase during pregnancy in rats, and urinary nitrate/nitrite excretion has been reported to increase. NO synthase inhibition in pregnant rats produces HTN associated with peripheral and renal vasoconstriction, proteinuria, intrauterine growth retardation, and increased fetal morbidity, closely resembling the symptoms of human PIH. Iimmunological factors could also contribute to preeclampsia including HLA class I antigens (HLA-A, HLA-E, and HLA-G), helper T cells, natural killer cells, and complements.

Drug-Induced Hypertension

Numerous therapeutic and illicit drugs, as well as some commonly used dietary supplements, may influence BP significantly, especially in individuals whose BP regulation is already disturbed. A detailed discussion of the many substances with effects on BP would be beyond the scope of this chapter.

Normative Blood Pressure Values in Children and Adolescents

Casual Blood Pressure Measurement

In 2017, the American Academy of Pediatrics (AAP) published its first clinical practice guidelines (CPG) for screening and management of BP in children and adolescents [80]. This was an update to the 2004 guidelines previously published by the National High Blood Pressure Education Program Working Group in the USA [81]. There were several key updates in the 2017 AAP CPG regarding casual BP measurement. First of these updates was that for adolescents 13–17 years old, the BP category threshold values were no longer the percentile based, but instead matched those of 2017 American Heart Association (AHA) and American College of Cardiology adult HTN guidelines. Second, the normative BP tables based on age, gender, and height were revised to include only the auscultative BP measurements from normal-weight children rather than the previous normative data that included overweight and obese children. Third, the threshold value definition for stage 2 HTN for 1- to 12-year-old children changed from ≥99th percentile +5 mm Hg to ≥95th percentile +12 mm Hg. Lastly, the category named "prehypertension" was replaced by "elevated BP."

The most recent European pediatric guidelines were published in 2016 by European Society of Hypertension (ESH) [82]. Some of the unique aspects these guidelines with regards to casual BP include percentile-based BP categories for 0- to 15-year-olds, and adult definitions and threshold values for ≥16-year-olds, a category called "high normal" to mirror "elevated BP" category, and a distinct category called "isolated systolic HTN." The ESH guideline uses the same data source as the US 2004 guidelines, and stage 2 HTN threshold value for 0- to –15-year-olds remained ≥99th percentile +5 mm Hg. ▶ Chap. 63, "Evaluation and Management of Hypertension in Children" provides more detailed discussion on definition, categories, standards, and other aspects of casual BP measurements.

Ambulatory Blood Pressure Monitoring

Ambulatory BP monitoring (ABPM) is a more comprehensive method to evaluate BP in both adults and children and is most often performed for a 24-h period. Advantages of ABPM over casual BP include reproducibility, better correlation with hypertensive target organ changes, and cost effectiveness [83]. ABPM is optimal in diagnosing children with white coat HTN (WCH) and masked HTN (MH) [83]. The 2017 AAP CPG expanded the recommended uses of ABPM to include A) confirmation of HTN after casual BP measurements in the elevated BP category for 1 year or with stage 1 HTN readings over three clinic visits, B) assessment of HTN severity in children and adolescents with high-risk conditions and determine if abnormal circadian BP patterns are present, C) evaluation for suspected WCH, D) detection of HTN (including MH) in patients who have undergone coarctation repair, E) assessment of treatment effectiveness especially when clinic and/or home BP measurements indicate insufficient BP response to treatment, and F) monitoring of CKD with HTN patients to lower 24-h mean arterial pressure (MAP) <50th percentile [80].

ESH also endorses the use of ABPM in pediatrics in similar clinical scenarios and in high-risk patients such as DM, CKD, solid organ transplantation, severe obesity with or without sleep-disordered breathing, and assessment of HTN treatment efficacy. In addition, ESH guidelines recommend its use in children with hypertensive response during treadmill test, autonomic dysfunction, suspicion of catecholamine secreting tumors, and in clinical trials [82]. Parallel to casual BP measurements, ABPM threshold values to define BP categories are statistical based as discussed further below. The normative ambulatory BP values were derived from 1141 all Caucasian German children and adolescents and later reanalyzed by using the least mean square method to create the normative table [84].

The major disadvantages of current ABPM practice include lack of availability of ABPM across the world especially in low- to middle-income countries, and limitation of normative BP tables due to the limited data for small children and lack of ethnic and racial diversity of the normative data.

Home Blood Pressure Measurement

While ABPM has many advantages, monitor availability for pediatricians around the world is a major limitation. In adults, self-measurement of home BP is regarded as an alternative and has been recommended in clinical practice guidelines [85]. Like many ambulatory BP monitors, home monitors are oscillometric devices. There is pediatric data for home BP measurements including reproducibility, validation, and reference values [86]. Using ABPM as the reference method, sensitivity, specificity, and positive and negative predictive values of home BP measurements for the diagnosis of HTN were 55, 92, 74, and 82%, respectively; for the diagnosis of WCH 89, 92, 70, and 98%, respectively; and for the diagnosis of MH 36, 96, 50, and 93%, respectively [87].

Clinical practice guidelines for home BP monitor usage differs between the latest ESH and AAP guidelines. The ESH endorses its usage [82], while the AAP CPG recommends avoidance of home BP monitoring for diagnosis of HTN, WCH, and MH, while they endorse its use as an adjunct to casual BP and ABPM after HTN diagnosis is established [80]. Website https://www.stridebp.org/bp-monitors maintains an updated list of pediatric validated home BP monitors.

Definition of Hypertension in Children

Casual Blood Pressure Measurement

In contrast to adults, children and adolescents rarely suffer from hypertensive cardiovascular events, and HTN definition threshold values are statistically defined rather than outcome based. Diagnosis of HTN is made only if a child or adolescent has auscultatory confirmed BP readings ≥95th percentile on at least three different visits [80, 82]. The 2017 AAP CPG endorses the use of pediatric validated automated oscillometric devices for casual BP measurement, but when abnormal BP is detected (≥90th percentile or >120/80), confirmation by average of two auscultatory BP measurement is recommended to define the BP category [80]. As mentioned above, one of the major updates of the 2017 AAP CPG was the exclusion of BP measurements from overweight and obese healthy children for its data source to create the new normative tables [80]. This resulted in reduction of 2–3 mmHg for corresponding percentiles for most younger children. Another update of the 2017 AAP CPG is the use of adult BP categories for adolescents ≥13 years old [80]. ESH guideline recommends the use of adult BP categories for adolescents ≥16 years old [82]. Implication of these definition changes in adolescents is the increase of respective threshold values, especially in shorter adolescent females. For example, the 95th percentile systolic BP for a 16-year-old female with fifth percentile height is 124 mmHg, but in the newer guidelines, the threshold value for stage 1 HTN is now higher at 130 mmHg.

Ambulatory Blood Pressure

ABPM provides additional BP data such as mean systolic BP, mean diastolic BP, and MAP for the entire 24 hours, awake hours, and sleep hours. Both AHA and ESH recommend the use of the 95th percentile values ("gender and age" or "gender and height" tables are available) from Wühl et al. [84] as the threshold values to define HTN. ESH guideline also specifies the use of adult threshold values (24 h: 130/80 mmHg, awake 135/85 mmHg, sleep 125/75 mmHg) if the 95th percentile values are higher than these adult threshold values [82]. In addition, ABPM provides "BP load," defined as the percentage of BP readings exceeding the threshold values, and "nocturnal dipping," defined as the percentage difference between awake and sleep mean BP values ([mean awake BP – mean sleep BP]/mean awake BP x 100). The clinical significance of BP load is that higher load values may be associated with left ventricular hypertrophy [88], and BP load is now part of the staging schema in the most recent AHA ABPM scientific statement [83]. This statement suggests the use of casual BP and ABPM data, including mean awake and sleep SBP and DBP, and awake and sleep SBP and DBP loads, to determine BP categories of normal BP, WCH, prehypertension, MH, ambulatory HTN, and severe ambulatory HTN. Normal nocturnal dipping is defined as ≥10%, and blunted nocturnal dipping is defined as 0–10%, and reverse dipping is defined as mean sleep BP higher than mean awake BP. Abnormal nocturnal dipping has been associated with microalbuminuria in children with type 1 DM [89], and ABPM use to evaluate nocturnal BPs are recommended in high-risk patients such as those with DM, CKD, solid organ transplant, and severe obesity [83]; the current guidelines, however, do not include nocturnal dipping as part of the aforementioned BP staging schema.

Lastly, although MAP is currently not part of the current BP staging schema, one pediatric study reported an increase of HTN detection by 19% when MAP was used in the definition of HTN, and the authors suggested the inclusion of MAP in the definition of ambulatory HTN since most ABP monitors are oscillometric devices and actually measure MAP rather than systolic and diastolic BP [90]. There is one specific clinical scenario when 24-h MAP from ABPM is of clinical use currently. The ESCAPE trial demonstrated that tighter BP control defined by 24-h MAP <50th percentile resulted in slower decline in renal function compared to MAP in the 50th–95th percentile range in pediatric CKD patients [91]. And therefore, the 2017 AAP CPG recommends the use of ABPM in children and adolescents with CKD and HTN to guide treatment to achieve 24-h MAP <50th percentile [80].

Epidemiology of Hypertension

Prevalence of Hypertension in General Population

If the 95th percentile from the normative table is used as threshold values, by definition, 5% of children will be diagnosed as hypertensive. However, BP measurements obtained to formulate the normative data were from first time visits for each child. In clinical settings where repeat BP measurements take place, the prevalence of confirmed HTN is lower partly due to inherent BP measurement variability, accommodation effect, and tendency for regression toward the mean phenomenon. There have been many pediatric HTN prevalence studies around the world, but comparison among different regions is difficult due to nonstandardized methods to diagnose HTN. However, Song et al. screened 9084 records and performed meta-analysis of 47 articles from around the world that used the 2004 Fourth report BP definitions and at least three separate BP measurements. Table 3 summarizes some of the main findings from this meta-analysis. Overall global pediatric prevalence rate of HTN was 4% with an additional 9.7% with prehypertension (equivalent to "elevated BP" or "high normal") [92]. World Health Organization–defined region-specific rates were as follows: Africa 6.9%, Americas 3.0%, Eastern Mediterranean 5.3%, European 4.1%, Southeast Asia 3.1%, and Western Pacific 4.6% with no statistical differences between these regions. There were also no statistical differences in prevalence rates based on gender, and urban versus rural settings. There was a clear pattern of increasing prevalence rates of HTN with increasing body mass index group with normal weight group prevalence rate of 1.9%, overweight group rate of 5%, and obese group rate of 15.3%. Perhaps most concerning finding is the clear pattern of increasing prevalence rates over the years: prevalence rate in the 1990s was 1.3%, 2000s was 3.3%, and 2010–2014 was 6%.

Following the same trajectory, more recent US studies have reported HTN prevalence of approximately 3.5% and "prehypertension" of approximately 2–3.5% [93, 94], an increase from earlier reports of around 1% or lower. As for abnormal BP measurements (both HTN and prehypertension categories) based on single measurements, the US National Health and Nutrition Examination Survey has reported 15–19% for boys and 7–12% for girls with higher rates among Hispanic and non-Hispanic African Americans compared to non-Hispanic Caucasians [95].

Multiple European studies have reported prevalence rates with central Europe having similar rates as the USA, and southern European studies demonstrating higher rates. Adolescent HTN prevalence rates were reported as 2.2% in Switzerland, up to 4.9% in Poland [94, 96], and in Greece and Portugal, they were in the range of 12–14% [97, 98].

At this time, there has not been any new prospective studies to report the updated pediatric HTN prevalence based on the 2017 AAP CPG definitions, but several publications have addressed potential implications mostly by cross-sectional study design. These studies had different subject selection and population: the US NHANES cohort, Chinese school-based screening, and high-risk adolescents. They showed modest increase in prevalence of high BP measurements and HTN of approximately 1–5% when applying the different definitions from the 2017 AAP CPG versus 2004 Fourth Report [99–102]. These studies also noted an increase in the likelihood of upward reclassification of BP categories for males, and obese participants. The 2017 AAP CPG definitions were also applied to American school–based screening program data. The prevalence of high BP increased by 1.5% (16.3 versus 14.8%) when applying the 2017

Table 3 Pediatric hypertension and prehypertension prevalence rates around the world: global overall and World Health Organization designated regions

	Hypertension (%)	Prehypertension (%)
Overall	**4.00**	**9.41**
Africa	6.94	
Americas	3.02	9.79
Eastern Mediterranean	5.26	
European	4.09	9.08
Southeast Asia	3.10	
Western Pacific	4.64	

BP category definition from the 2004 Fourth report. Data are extracted from reference [141]

AAP CPG compared to the 2004 Fourth Report, but the overall combined stage 1 and 2 prevalence of HTN decreased slightly from 2.7% to 2.3% [103]. The authors hypothesized that these reclassifications were likely due to a combination of lowering BP threshold values for most of the <13-year-old cohort and implementation of the standard adult threshold value of 130/80 for ≥13-years-old cohort, which had either increased or decreased threshold values depending on adolescents' age, gender, and height.

Lastly, incidence of pediatric HTN data is limited due to challenges of long-term longitudinal follow-up with requirement of multiple BP measurements. Redwine et al. reported overall incident rate of 0.5%/year from a multiethnic American school–based BP screening program of ages 10–19 years old using the 2004 Fourth report BP definitions, with higher rates of incidence if they were originally in the category of "at-risk" or "pre-hypertension" [104]. This rate may sound small, but in a population of 100,000 adolescents, this incident rate would translate to 1500 adolescents with new HTN diagnosis in 3 years.

Prevalence of Hypertension in Special Population

There are numerous pediatric chronic diseases where HTN prevalence rates have been reported to be significantly higher compared to the healthy general population with a number of these populations discussed in this section. From a large American multicentered observational cohort study, Chronic Kidney Disease in Children study (CKiD) where 69% of the cohort was on antihypertensive medication at the time of ABPM, HTN was diagnosed by ABPM in 52% [105]. Of these hypertensive CKD children, 37% were diagnosed to have MH, and only 4.1% were diagnosed to have WCH. This CKiD cohort also demonstrated that proper diagnosis and treatment of HTN is of the essence as there were significantly higher rates of LVH in hypertensive CKD patients compared to normotensive CKD patients [106].

In children who had successful coarctation repair at a median age of 24 months, in a cross-sectional study with a median age of 14.5 years old, 45% of the cohort was found to have MH by ABPM [107].

In DM where early onset of CVD is of significant concern, rates of HTN appear to be higher in children and adolescents with type I and II DM. In an European single center cross-sectional analysis of type I DM patients with a median age of 14.9 years old, 51% had hypertensive BP measurement (≥95th percentile), and 29% had ABPM confirmed HTN [108]. In an American multicentered multiethnic longitudinal follow-up of type II DM adolescents where all participants had <2 years of diabetes diagnosis duration, HTN prevalence was 12% at baseline, and 34% by end of study 3.9 years later [109].

In the solid organ transplant population, post-kidney transplant cohort has been most frequently studied. Common HTN risk factors in solid organ transplantation recipients include the use of immunosuppressive medications known to raise BP, such as corticosteroids and calcineurin inhibitors, and an increase in the risk of metabolic syndrome, and various degrees of CKD. In post-kidney transplant children and adolescents, the prevalence of HTN has been reported to range between 60% and 90%, with LVH reported in 50–80%, and relatively poor control of HTN with only 20–50% of treated children reaching normal BP [110]. The data is more scant for non-kidney solid organ transplantation. Registry of pediatric post-liver transplantation reported elevated BP measurement (≥95th percentile or on antihypertensive medication) prevalence of 17.5–27.5% during their annual follow-up between years 5 and 10 post-transplant [111]. According to the registry of the International Society for Heart and Lung Transplantation, nearly 70% of pediatric heart transplant recipients were diagnosed with HTN at 5 years post-transplant [112].

Finally, there are genetic conditions known to be associated with HTN including Turner syndrome and neurofibromatosis type I. HTN is a well-known major risk factor for CVD in adult women with Turner syndrome, but very little pediatric prevalence data is available. In a single-centered British study with 62 females aged 5–22 years old, 24-h ABPM found 21% of patients with mean systolic, and 17% with mean diastolic measurements above the 95th percentile for age and gender [113]. In a single-centered Italian study with 27 patients aged 4–24 years old and followed for 2–10 years at least annually for neurofibromatosis type II, the HTN prevalence rate was 19% [114].

Prevalence of White Coat Hypertension

There have been several studies that have reported prevalence of pediatric WCH with widely varied percentages partly due to changing casual BP category definitions and ABPM BP staging schema over time. Earlier US studies with different ABPM definitions reported the prevalence of WCH to be around 50% of referred patients for elevated BP [115, 116], but these studies did not use BP load data from ABPM as part of the BP staging schema. Another ABPM study demonstrated that when BP load was included in the diagnostic schema, rates of WCH decreased from 45% to 22% [117].

Adult WCH outcome data show mixed results, and WCH may represent a risk factor for eventual progression to sustained HTN [118] and may serve as an intermediate risk factor for both hypertensive target organ damage and cardiovascular events [119]. Pediatric WCH data is even more scant. One small study in Sweden demonstrated that 23% of children initially diagnosed with WCH progressed to sustained HTN with median follow-up time of approximately 9 year, although obesity may have played a major contribution [120]. This study also demonstrated that pulse wave velocity and carotid intimal-medial thickness were significantly higher in those who progressed to sustained HTN compared to those who remained as WCH, while there was no difference in left ventricular mass index. As for target organ changes, the risk for left ventricular hypertrophy in WCH is not increased compared to normotensive children, but left ventricular mass index may be intermediate between normotensives and sustained hypertensives after controlling for body mass index [115, 121].

Prevalence of Masked Hypertension

MH is the converse of WCH where patients have below the threshold BP readings in a clinic-based setting but have above-threshold readings in out-of-clinic settings. In the adult population, MH prevalence has been estimated to be ~9–17%, and the cardiovascular risk associated with MH approaches the risk associated with sustained HTN [122]. Pediatric studies have reported prevalence of ~8–17% in healthy children [123, 124], and 9% among children referred for BP evaluation [125]. Risk factors for MH in these studies include obesity and family history of HTN. Although no pediatric data exist for cardiovascular events with MH, these studies have also demonstrated increased left ventricular mass index in children and adolescents with MH [123–125]. In children and adolescents with chronic conditions, including those after coarctation or aorta repair, CKD, post-solid organ transplantation, and sickle cell disease, MH has been reported to be much higher [105, 107, 126–128]. And thus, the most recent AHA pediatric guideline recommends routine use of ABPM for evaluation of MH in a) clinical suspicion of HTN but normal or elevated BP clinic measurements, b) DM, c) CKD, d) solid organ transplant, and e) severe obesity with and without sleep-disordered breathing [83].

Conclusion

During the decades, there has been increasing interest and progress in the field of HTN in children and adolescents. Emerging new techniques may provide insights into the pathophysiology of HTN and generate new hypothesis. Future epidemiological studies should aim at defining HTN in relation to target organ damage. Large population-based studies are also needed to investigate whether various intervention methods prevent development of HTN and CVD in the adulthood.

Abstract

Hypertension is an increasingly common and important problem in children. This chapter provides a clinical approach to childhood hypertension based on current evidence. Frameworks for defining and classifying hypertension are provided in the context of two main international guidelines, produced by the American Academy of Pediatrics and European Society of Hypertension. Included are recommendations about how best to measure BP and the role of ambulatory blood pressure monitoring.

The approach to evaluating hypertension continues to evolve, reflecting changes in test accuracy and the pretest probability of secondary hypertension. Available tests and indications for ordering these are discussed in the context of presenting signs and symptoms. Both non-pharmacologic and pharmacologic therapies are covered. Dietary interventions and exercise are both utilized in all children with hypertension, but particularly in the setting of obesity. The rationale and thresholds for pharmacologic therapy are discussed, along with recommendations about the treatment of children with secondary or severe hypertension. The chapter concludes with discussion of unanswered research questions and needs.

Blood pressure · Primary hypertension · Monogenic hypertension · Secondary hypertension · Left ventricular hypertrophy · Ambulatory blood pressure monitoring

Introduction

The prevalence of hypertension (HTN) among children is increasing, driven by an increase in primary HTN, observed in conjunction with the global obesity epidemic [1–3]. While the principles of diagnosis and management have not changed substantially, they have shifted to better include children with primary HTN while ensuring that children with secondary HTN are not missed.

The most commonly used guidelines are those from the American Academy of Pediatrics (AAP) and European Society of Hypertension (ESH) [4–6]. As reviewed below, there are some key differences between the two guidelines, but they largely agree regarding the methods used to diagnose and treat children with HTN.

Definitions and Classification

Blood pressure (BP) levels used to define HTN in adults have recently been revised [7, 8]. They are based on the results of long-term studies that have demonstrated an increase in the number of adverse events such as myocardial infarction, stroke, and sudden cardiac death with higher BP levels. Given that these events occur only rarely in the pediatric population, it is not possible at present to define childhood HTN based on outcomes. Therefore, a statistical approach has been adopted that defines abnormal BP levels in children and adolescents according to the distribution of BP in healthy children.

The BP classification schemes of the AAP and ESH pediatric guidelines are summarized in

Table 1 Blood pressure categories in AAP and ESH guidelines

European guidelines			US guidelines		
	<16 years	≥16 years		<13 years	≥13 years
Normal BP	<90th %ile	<130/85	Normotension	<90th %ile[a]	<120/80
High-normal BP	≥90th %ile–<95th %ile	130–139/85–90	Elevated BP	≥90th %ile[a]–<95th %ile	120–130/80
Grade I HTN	≥95th %ile–99th %ile + 5 mmHg	140–159/90–99	Stage I HTN	≥95th %ile–<95th %ile +12 mmHg[b]	130/80–139/89
Grade II HTN	>99th %ile + 5 mmHg	160–179/100–109	Stage II HTN	≥95th %ile + 12 mmHg[c]	≥140/90
Isolated systolic HTN	SBP>95th % ile and DBP <90th %ile	SBP >140 and DBP<90	Isolated Systolic HTN	Not addressed	Not addressed
Immediate referral to emergency care	Severe HTN[d] associated with life-threatening condition	Severe HTN[d] associated with life-threatening condition	Immediate referral to emergency care	>95th %ile + 30 mmHg[e]	>180/120 ¥

US United States, *BP* blood pressure, *SBP* systolic blood pressure, *DBP* diastolic blood pressure, *HTN* hypertension

[a] Or 120/80, whichever lower

[b] Or 130/80–139/89, whichever lower

[c] Or 140/90, whichever lower

[d] Defined by some as 20% above Grade II limit

[e] Or stage II with symptoms

Table 1 [9]. As can be seen, there are common features, including use of the 90th percentile to denote the upper limit of normal BP in children (up to 13 years in the AAP guideline, and up to 16 years in the ESH guideline), and use of the 95th percentile to denote HTN (up to 13 years in the AAP guideline, and up to 16 years in the ESH guideline). The other major similarity is adoption of static cut-points for diagnosis of HTN in adolescents [4, 5]. In the case of the AAP guideline this was done to align the pediatric guideline with the corresponding adult guideline, which was in development at the same time as the pediatric one [10].

However, as has been pointed out by others [9, 11, 12], there are notable differences as well, with the two major ones being the normative BP data used, and the second being the difference in age at which adult BP cut-points were adopted. The 2017 AAP guideline was essentially an update of the 2004 “Fourth Report” issued by the United States National High Blood Pressure Education Program [13]; that document contained normative BP data tables based on a population that contained a high percentage of children with overweight and obesity. The AAP commissioned new normative BP data tables based only on children of normal weight [4]. This change resulted in BP values that were roughly 2–3 mmHg lower for each age/sex/height group compared to those in the Fourth Report. The ESH pediatric guideline [5, 6] adopted the Fourth Report normative data, leading to differences in BP classification, most notably that the AAP guideline classifies as hypertensive youth with overweight and obesity who would be classified as non-hypertensive by the ESH criteria. The implications of this difference in classification have been discussed in detail elsewhere [12, 14]. (Both the 2004 Fourth Report and the 2017 AAP BP tables are freely available online, so are not reproduced here.)

As seen in Table 1, the AAP guideline adopts adult cut-points for adolescents starting at the age of 13 years – this was chosen because the 90th percentile BP values for teens in the new normative data tables approximated the lower adult cut-points in the AHA-ACC guideline starting at 13 years of age for both boys and girls [4, 10]. In the ESH guideline, the age of 16 years was chosen because the 95th percentile for boys of that age equaled the cut-points in the ESH adult guideline. In both guidelines, the static cut-points were applied at the same age in boys and girls. In combination with the lower cut-points in the adult and pediatric American (AAP, AHA/ACC) guidelines compared to the adult and pediatric European guidelines, following the AAP guideline will result in classification of more teens between 13 and 16 years of age as hypertensive compared to following the ESH guideline. The implications of this difference require further study, particularly correlation of a HTN diagnosis with intermediate outcomes such as left ventricular hypertrophy (LVH) and vascular changes (increased pulse wave velocity, increased carotid intimal-medial thickness), so that a definitive recommendation can be made regarding which set of guidelines is most appropriate for general use worldwide.

Blood Pressure Measurement

Although evolving technology can offer the means to measure complex functions of cardiovascular (CV) physiology, it is worth emphasizing that the basic phenotype remains BP. More importantly, all other measurements are meaningless unless BP is measured accurately. BP is a physiologic parameter which has different values along the vascular tree. It is characterized by continuous dynamic fluctuations that are the result of a complex interplay among environmental, physical, and emotional factors, all inducing BP changes [15]. Variability in BP, from a clinical viewpoint, can be seen as a source of noise that creates difficulties in assessing the individual's "true" BP level, introducing uncertainty into the assessment of a subject's BP status. This is especially true when spot clinic measurements are used [16]. These are the fundamentals for developing methods to measure BP at different points in the vascular tree, brachial or aortic root, and for establishing different protocols for office and out-of-office BP assessments [4–6].

The different approaches, beginning with how to assess BP values and following with the number and conditions of the procedure, are major issues of controversy since the results are not always in concordance. Office BP is the basis for HTN screening and diagnosis, and despite the increasing use of out-of-office BP, the former remains indispensable for defining BP phenotypes. Office BP is a widely available, permitting universal, regular screening for HTN in the pediatric age group, which is recommended from the age of 3 years old by current pediatric guidelines [4–6]. The type of the device, oscillometric or auscultatory, the number of readings per visit, the number of visits, and the reference values used to classify BP conditions are still matters of debate.

In recent years, there has been a fundamental change in the methodology for measuring office BP. As the traditional auscultatory technique requires a sphygmomanometer, a stethoscope, and a trained observer, the automated oscillometric measurement has been introduced. This measurement requires a validated device that may provide the average of a number of measurements and little training for the observer. In the auscultatory method, Korotkoff sounds are used to assess SBP (K1) and DBP (K5) while deflating the cuff [16]. Oscillometric devices measure mean BP directly from the point of maximum oscillation; neither SBP nor DBP are measured directly, but are calculated using an algorithm based on a putative relationship between the oscillations [17]. If an oscillometric method is applied, the monitor should have passed the validation procedure recommended by the British Hypertension Society [18], the American Association for the Advancement of Medical Instrumentation [19], or the ESH International Protocol [20]. Values obtained with an oscillometric device are considerably higher than those obtained by auscultatory ones. Therefore, if HTN is detected by the oscillometric method, it is recommended to be confirmed it by the auscultatory one [4–6]. Recent studies have proposed reference values using oscillometric devices [21–23]. Unfortunately, the heterogeneity of the studies, as well as differences in manufacturers' algorithms, does not permit pooling the information.

Evolving data form cohort studies based on office BP at childhood and adolescence show an incremental risk of HTN and subclinical target organ damage in early adulthood, confirming the prognostic significance of office BP measurement [24, 25]. Office BP, despite its persistence as the main reference for BP classification and HTN management, may offer limited insight into the variability and patterns of BP under living conditions. To reduce variability induced by the presence of physicians or nurses, unattended BP measurement has been introduced in the last several years, but pediatric experience is limited [26–29].

Ambulatory Blood Pressure Monitoring

The role of ambulatory BP monitoring (ABPM) over 24 h has been increasingly recognized since it offers a more representative observation of BP levels, not only allowing for a large number of measurements in a regular life environment, both day and night, during activity and while at rest, but it is also an assessment of the circadian profile [30]. ABPM is now increasingly recognized as providing useful information for the diagnosis and management of HTN and has contributed significantly to our understanding of HTN by "unmasking" BP phenomena that were not readily apparent using office BP. Values obtained using 24-h ABPM have a higher reproducibility and better relationship with the presence of organ damage than do those obtained using office BP [31–33]. Although some concerns exist about the superiority of ABPM over office BP, claiming that a mathematical artifact can explain the differences, the role of ABPM in pediatric HTN has been established, and further reinforced by the latest pediatric guidelines.

The classification of ABPM categories is based on reference values from a European study [31], which have been used as the basis of the recommended definition of HTN in the guidelines. Despite the limitations of ABPM such as observers' expertise, normative tables [34], and monitor validation, there is a consensus that the diagnosis of HTN should be confirmed by ABPM to avoid treatment for white-coat HTN. Moreover, children and adolescents with suspected masked HTN or with high-risk conditions should undergo ABPM to evaluate whether an abnormal BP phenotype exists. Repeated ABPM in research studies has established that ABPM can provide useful prognostic information. This is the case of masked HTN as a forerunner of sustained HTN [35], the risk to develop nephropathy in type 1 diabetes [36], and the relevance of strict BP control and the progression of renal failure [37]. Even in the clinical setting, repeated ABPM can be useful to determine the stability of an individual patient's BP phenotype [28].

In clinical practice, the averages of 24-h diurnal and nocturnal BP are the recommended parameters for defining HTN status and for monitoring the BP-lowering effect of antihypertensive agents. In a meta-analysis of ten long-term outcome studies performed in more than 8000 adults, BP load did not add significantly to the CV risk associated to the mean 24-h BP level [38]. The night-to-day BP ratio represents circadian variability due to the physiological nocturnal BP fall. A nocturnal BP fall of >10% of daytime values (night-day BP ratio <0.9) can be accepted as an arbitrary cut-off to define normality [15]. Abnormal circadian variability has been associated with sleep disturbance, obstructive sleep apnea, obesity, high salt intake in salt-sensitive subjects, autonomic dysfunction, chronic kidney disease, and diabetes, both type 1 and type 2 [5, 6, 32, 39]. The prognostic significance of reduced circadian variability has been claimed as a result of an association with increased organ damage. Nevertheless, resolving the circadian abnormality has not been accepted as a target [40].

The intraindividual differences between office and out-of-office BP values, white-coat and masked HTN, are the strengths of ABPM as a diagnostic tool. The reported frequency of white-coat HTN varies, perhaps as a result of the criteria used to establish the diagnosis [41]. At present, no long-term follow-up data are available for children with white-coat HTN at initial assessment, in order to know the reproducibility and the real impact of this condition. Hence, it remains to be clarified whether white-coat HTN is an innocuous phenomenon or a prelude to future sustained HTN. The inverse phenomenon, masked HTN occurs in approximately 10% of children and adolescents [42–44]. The persistence and clinical significance of the phenomenon has shown that in 40% of children, the abnormal elevation of the daytime ambulatory BP persisted over a minimum

Table 2 Recommendations for 24-h ambulatory BP measurements

During the process of diagnosis
Confirm hypertension/Detect white-coat hypertension Target organ damage (LVH, microalbuminuria) and office BP normal (masked hypertension) Type 1 and Type 2 diabetes Chronic kidney disease Renal, liver, or heart transplant Coarctation of the aorta (repaired) Severe obesity with or without sleep-disordered breathing Hypertensive response during the treadmill test Discrepancy between office BP and home BP
During antihypertensive drug treatment
Evaluate for apparent drug-resistant hypertension Assessment of BP control in children with target organ damage Symptoms of hypotension
Clinical trials
Other clinical conditions
Autonomic dysfunction
Suspicion of catecholamine-secreting tumors

Ref: Lurbe et al. [5, 6], Flynn et al. [4]

of 6 months [42]. Masked HTN has been linked to progression to HTN in youth, with the risk being higher in boys than in girls [35]. Masked HTN warrants follow-up, and if it persists, left ventricular mass should be assessed. Recommendations by scientific organizations on the use of ABPM in the process of diagnosis and evaluation treatment have been developed during the past several years and are summarized in Table 2.

Other Approaches to Blood Pressure Assessment

The role of home BP monitoring (HBPM) has been less assessed, and its use during the process of HTN diagnosis is not currently supported. Its routine use, however, is recommended by expert opinion' for the follow-up of chronic pediatric HTN subjects, when strict BP control is mandatory [4–6]. It is noteworthy that HBPM presents both lower sensitivity and positive predictive value in children and adolescents when predicting masked HTN compared to those for ABPM, although a good performance at assessing for white-coat HTN has been reported [45, 46]. This finding supports the recommendations for its use in a complementary role between regular ABPM in hypertensive pediatric patients for pharmacological treatment dose titration, assessment of BP control, and the timing of repeat ABPM. Home BP has been reported as lower than daytime ABP in children and adolescents, while the relation between home and office BP showed inconsistent patterns among studies, dependent on age, BP elevation, and office BP measurement method [47]. Several issues about the clinical application of the method, including validated devices, remain under-investigated. However, the provision of guidance regarding the proper methodology for reliable home measurement [5, 6] could help identify more children at increased CVD risk and has the potential to move the field forward [9].

Although less widely studied, the evaluation of central BP (cBP) in children and adolescents is also important because pulse pressure amplification between central and peripheral sites is greatest in youth. Mean and diastolic BP are nearly constant throughout the arterial tree, but systolic BP changes, with peripheral being higher than central or aortic BP [48]. Compared with adults, this phenomenon differs significantly in children, whose systolic BP amplification is substantial, almost twice that of adults [49]. If central systolic BP relates more closely than peripheral systolic BP to target organ damage, including LVH as some claim in adults [50], it may be very useful clinically to estimate its values in children. Nevertheless, its benefit and independence from peripheral BP remains unknown. In order to obtain an indirect assessment of hemodynamic parameters in the aortic root, noninvasive methods have been developed over the last few years. Consequently, the assessment of cBP has increased and has been introduced into many specialized clinics. The challenge of using cBP in children and adolescents is the absence of grounded reference values for classifying a given cBP as "normal" or not. In addition to the lack of reference cBP values, the high variability of the amplification phenomenon between aortic and brachial systolic BP at all ages [51] leads to a more difficult interpretation. Although more research is necessary in the future, cBP can help to identify the different phenotypes of people with isolated systolic HTN [52, 53]. In a recent study [54] the cuff-based radial tonometry and transfer function method has demonstrated its superiority over oscillometric devices in the assessment of central BP. The study also validates that the transfer function developed in adults is also valid in children.

Simultaneous assessment of peripheral and cBP has identified a condition that is called "pseudo" or "spurious HTN." O'Rourke was the first to describe this condition in six young males aged 14 to 23 years [55] characterizing it by a high peripheral systolic BP with "normal" central systolic BP and attributed to exaggerated pulse pressure amplification from central to peripheral arteries due to increased vascular elasticity. It is furthermore claimed to be probably a benign condition, although one recent study showed that almost one-quarter of youth with so-called spurious HTN developed sustained HTN on repeat ABPM after one year, and 51% evolve to white-coat HTN or normotension [56].

The potential value of central systolic BP and central pulse pressure in the assessment of adolescents with isolated systolic HTN is controversial. Central BP may be especially relevant in asymptomatic children incidentally found to have isolated peripheral systolic HTN without target organ damage [5, 6]. In children and young adults at high risk of future adverse CV outcomes (e.g., with primary HTN or chronic kidney disease), research is needed to ascertain not only which factors determine systolic amplification but also interventions that have a differential impact on central rather than peripheral systolic pressure [57]. Because of their high correlation, assessment of cBP will only offer incremental value over peripheral BP measurement if cBP proves superior at identifying target organ damage.

Blood Pressure During Exercise

Assessing BP during exercise has an established role in the evaluation of HTN and CV prognosis in adults, but fewer data examining its role are available in children and adolescents. BP measurements taken during exercise testing provide valuable information on a potentially inadequate hemodynamic response to acute exercise.

Calculated heart rate and systolic BP during exercise are positively associated with future resting BP in longitudinal studies [58, 59]. Likewise, an exaggerated systolic BP during exercise has also been reported in children at risk for early damage in vascular structure and functioning [60, 61] while an exaggerated BP response to treadmill exercise has been observed in children with white-coat HTN [62]. Despite these association studies, the clinical usefulness of BP response to exercise testing in children and adolescents is limited by the absence of reference values that include children and adolescents, which only exist for those 12–17 years old [63]. The ESH Guideline for HTN in adults suggest performing 24-h ABPM in subjects with a hypertensive response during the treadmill test searching for the possible presence of masked HTN [8]. Even though evidence in youth is lacking, this recommendation can be considered in adolescents.

Diagnostic Evaluation

The potential causes of HTN in childhood are broad and discussed at length in ▶ Chap. 62, "Pathophysiology and Epidemiology of Hypertension in Children." This requires a careful history and examination. This includes an awareness of syndromes associated with HTN due to renal, cardiac, endocrine, or other causes. Both recent pediatric guidelines [4–6] have detailed discussions of differential diagnosis and characteristic physical exam findings, which the interested reader should consult for additional guidance.

The changing epidemiology of childhood HTN has meant a revision in the suggested diagnostic evaluation. Both the AAP and ESH guidelines recommend a focused first-line screen in the absence of signs or features to suggest secondary disease, which would include age ≤5 years, stage 2 HTN, or a failure to adequately control BP with a single agent. Common components of the AAP and ESH guidelines are: urinary tract ultrasound, urinalysis, blood urea, serum electrolytes, and creatinine. A lipid screen and echocardiography for end organ damage are also recommended. Other tests, including plasma renin and aldosterone, cortisol, metanephrines, and catecholamines, all fall under the category of second-line tests to be performed in selected cases only.

This change reflects the importance of interpreting results within the clinical context they are performed. Even if test performance is consistent across subgroups, which is often not the case, unless the test is very accurate then a low pretest probability will equate to a low post-test probability. Considering as an example the use of free plasma metanephrines to detect pheochromocytoma, which has a sensitivity and specificity of approximately 95% [64]: If the pretest probability is 1%, then the post-test probability following a positive result will be 16%. Otherwise put, in this setting 84% of all positive results will be a false positive.

Evaluation for Secondary Causes

It is important to first rule out common presentations that do not require extensive evaluation, such as incorrect BP measurement of BP or white-coat HTN. Pain is frequently the cause of HTN in an inpatient setting, and treatment is best directed toward this rather the secondary increases in BP. Similarly, if volume overload is present then this need be identified and treated. After confirming that the child does have HTN requiring further investigation, it can be useful to consider potential causes by system.

Renal and Monogenic Causes of Hypertension

Renal parenchymal or vascular disease is the most common secondary cause of childhood HTN [65–67]. ▶ Chap. 64, “Renovascular Hypertension in Children: Evaluation and Management” details the evaluation of renovascular disease, so we will not review that here.

In most instances, a normal ultrasound, serum creatinine, and urinalysis are sufficient to rule out renal parenchymal abnormalities. While a negative or trace result on dipstick urinalysis has a high negative predictive value, if there is a strong index of suspicion or the urine is very dilute then a urine protein-to-creatinine ratio is appropriate [68]. An abnormal urine sediment may suggest glomerulonephritis, resulting in HTN due to activation of the renin-angiotensin-aldosterone system, sympathetic activation, and/or volume overload [69, 70]. Proteinuria and hematuria may also occur in the setting of thrombotic microangiopathy secondary to severe HTN, in association with hemolytic anemia, thrombocytopenia, and an elevated serum creatinine [71]. Less often the casual relationship is reversed, and atypical hemolytic uremic syndrome presents with HTN [72].

A dimercaptosuccinic acid (DMSA) scan may detect small renal scars not present on ultrasound, with abnormalities detected in 5–10% of children with a history of HTN but no history of urinary tract infection (UTI), including where other imaging modalities are unremarkable [73]. Whether these scars are the cause of HTN in the majority of these cases is unclear. While small parenchymal defects are common following childhood UTI, they usually do not result in clinical sequelae [74]. Hence, most centers will reserve DMSA scans for children with a history of recurrent febrile UTI or well-documented pyelonephritis.

An elevated plasma renin activity (PRA) or serum aldosterone may also point toward renal disease, or rarely a renin secreting tumor [75]. However, renal causes of HTN are usually detected on imaging and are not necessarily excluded by a normal PRA. Furthermore, an elevated PRA does not necessarily differentiate primary from secondary HTN [65, 76].

Low PRA values are important to identify because of an association with monogenic forms of HTN. These disorders mostly involve renal salt handling and steroid metabolism. Directed therapies exist, including mineralocorticoid receptor antagonists, epithelial sodium channel (ENaC) blockers, and glucocorticoids. Of note, these are not standard first-line agents and may not be used at all if the underlying diagnosis is missed. Beyond the evaluation of PRA, which based on the data available thus far appears to be reduced in most

Table 3 Monogenic disorders causing hypertension

	Inheritance	Age	K	Renin	Aldo	Urine steroid profile	Therapy
AME	AR	I, C, A	↓ or N	↓	↓	AbN	Spironolactone, eplerenone
GRA	AD	I, C	↓ or N	↓	↑ or N	AbN	Amiloride, triamterene, glucocorticoids
CAH	AR	I	↓ or N	↓	↓	AbN	Spironolactone, eplerenone
LS	AD	C, A	↓ or N	↓	↓	N	Amiloride, triamterene
GS	AD	C, A	↑ or N	↓	↑ or N	N	Thiazide

Modified from Ferguson and Flynn [195]

AME apparent mineralocorticoid excess, *GRA* glucocorticoid remedial aldosteronism, *CAH* congenital adrenal hyperplasia, *LS* Liddle syndrome, *GS* Gordon syndrome, *AR* autosomal recessive, *AD* autosomal dominant, *I* infancy, *C* childhood, *A* adulthood, *N* normal, *AbN* abnormal, ↓ decreased, ↑ increased

cases of monogenic HTN, the known disorders can be categorized based on the serum aldosterone level and other electrolytes (Table 3) [77–80].

A raised aldosterone level, low PRA, family history of HTN early in life and cerebrovascular accidents suggests glucocorticoid-remediable aldosteronism (GRA) [80].[15] GRA is inherited in an autosomal dominant fashion and was one of the first monogenic causes of HTN identified. The specific defect is a fusion of the CYP11B1 and CYP11B2 genes, resulting in an aldosterone synthase product that is responsive to adrenocorticotropic hormone (ACTH), and thus aldosterone levels are elevated and related to ACTH levels rather than PRA [81]. Overproduction of cortisol C-18 products is detectable in the urine and can establish the diagnosis in the absence of genetic testing. While GRA is a rare condition in the population overall, polymorphisms in the CYP11B1 and CYP11B2 are reported to have a digenic relationship to HTN [82].

Hyperkalemia with a low PRA, hyperchloremic acidosis, and normal or low aldosterone level suggests pseudohypoaldosteronism type II or Gordon syndrome [78]. Four underlying genes have been implicated, all resulting in increased sodium, potassium, and chloride resorption in the distal convoluted tubule [83, 84]. Mutations of cullin-3 (CUL3) tend to have a more severe phenotype and present in childhood, consistent with CUL3 being expressed throughout the nephron, including proximal convoluted tubule [83]. The other identified mutations, KLHL3 (recessive and dominant forms), WNK4, and WNK1, may present at any age, although the majority of causes are not identified until adulthood. Thiazide diuretics reverse the electrolyte abnormalities and lower BP in affected patients [83].

The presence of hypokalemia in conjunction with low PRA points to congenital adrenal hyperplasia (CAH), apparent mineralocorticoid excess (AME), or Liddle syndrome. In contrast to the most common form of CAH, 21-hydroxylase deficiency, which presents with salt wasting and hyperkalemia, 11β-hydroxylase and 17α-hydroxylase defects result in an accumulation of intermediate steroids with mineralocorticoid activity. Aldosterone is reduced, but deoxy-corticosterone (DOC) accumulates, activating the mineralocorticoid receptor, leading to sodium retention, HTN, and hypokalemia [85]. 11β-hydroxylase is associated with virilization or pseudoprecocious puberty, whereas 17α-hydroxylase is associated with under-virilization or female external genitalia in XY individuals [86]. In AME, a HSD11B2 gene mutation results in impaired 11β-hydroxysteroid dehydrogenase conversion of cortisol to cortisone within the kidney, the former and not the latter being capable of activating the mineralocorticoid receptor [87]. The urinary steroid profile will be abnormal in both CAH and AME, including an excess of the aforementioned metabolites [79, 88]. Licorice contains glycyrrhetinic acid, which inhibits 1β-hydroxysteroid dehydrogenase with high levels of consumption replicating AME [89, 90]. One final condition presenting with a low PRA and aldosterone is Liddle syndrome, caused by an upregulation of the epithelial sodium channel (ENaC) [91]. Consistent with the underlying mechanism, Liddle syndrome presents with hypokalemia, HTN, and alkalosis [77].

Autosomal dominant HTN with brachydactyly type E (HTNB) is a well-described syndrome caused by mutations of PDE3A encoding phosphodiesterase 3A [92, 93]. Different to the other causes of monogenic HTN discussed, PRA is normal and parathyroid hormone related peptide (PTHrP) is dysregulated [86].

Monogenic disorders of HTN are rare, both in the general population and pediatric HTN clinics where screening has been performed. Regardless, within increasing availability of genetic testing it may be that more children with monogenic disorders are identified and phenotypes further delineated.

Cardiac Causes of Hypertension

Coarctation of the aorta may present with HTN, and while many cases are detected antenatally, it is common that the diagnosis is not apparent until after birth [94]. Children may present with reduced femoral pulses and lower limb BP, but in children who do not have clinical signs of lower limb hypoperfusion the difference between upper and lower limb BP is not an accurate predictor of coarctation [95]. It is now recognized that HTN occurs frequently after coarctation repair, and is associated with CV events later in life [96–98]. Importantly, HTN among these children is often masked and thus regular ABPM recommended [4–6, 32, 39, 99].

Pheochromocytoma and Paraganglioma

Pheochromocytoma and paraganglioma (PPGL) are endocrine neoplasms that cause HTN by way of catecholamine production and release. Both are derived from neuroectoderm cells of the neural crest, but differ by location and propensity to catecholamine secretion [100]. Pheochromocytoma arise from chromaffin cells of the adrenal medulla and most secrete one or more catecholamines. Paraganglioma arise from autonomic ganglia, the paravertebral sympathetic ganglia, or the parasympathetic ganglia of the glossopharyngeal and vagal nerves within the neck and base of skull. Paraganglioma of the sympathetic ganglia are more likely to secrete catecholamines than those of parasympathetic ganglia, which may be relatively silent [101, 102]. PPGL are typically well-differentiated tumors, but a minority of cases develop distant metastases [103]. Pheochromocytoma are more common than paraganglioma [104, 105].

Given the diversity of tumor biology and overlap between normal and affected individuals for singular biomarkers, the use of multiple tests is required, usually including fractionated metanephrines (normetanephrine and metanephrine) and catecholamines (norepinephrine, epinephrine, and dopamine). Metanephrines are increasingly preferred for the detection of pheochromocytoma, as they are more stable analytes than catecholamines and are directly produced within pheochromocytomas by catechol-O-methyltransferase (COMT) [106]. Dopamine or its metabolites 3-methoxytyramine and homovanillic acid (HVA) may also need to be measured, as some paragangliomas secrete dopamine only [107]. The most accurate test is free plasma metanephrines after 30 min in the supine position [108, 109]. Seated testing may be used to rule out a PPGL, but because values among normal individuals are raised in the seated position by more than those with already elevated levels due to PPGL, it becomes more difficult to separate affected from nonaffected individuals [110, 111].

The largest prospective, diagnostic test accuracy study for PPGL found the sensitivity and specificity of free plasma metanephrines to be 99% (95%CI 96 to 100%) and 89% (95%CI 87 to 92%), respectively [109]. Fractionated urine metanephrines were nearly as sensitive (97%, 95%CI 92 to 99%), but not as specific (69%, 95%CI 64 to 72%). The accuracy of fractionated urine metanephrines may be close to that of plasma metanephrines in populations where the disease prevalence is high [108]. Urine total metanephrines and vanillylmandelic acid (VMA) are highly specific but not sensitive tests for PPGL [109]. The upper limit of normal for free plasma metanephrines is age dependent, with normetanephrine levels substantially higher among infants compared to older children [112].

Whereas mildly elevated catecholamine and metanephrines are common, a result greater than

3 to 4× the upper limit of normal, or elevation in both metanephrine and normetanephrine make a false positive less likely [109, 113]. Longitudinal trends may be useful in cases where there is an elevation less than 2× the upper limit of normal, increasing values potentially indicating PPGL [114, 115].

Medications are an important cause of false positive and negative results. Any drug that impacts catecholamine handling directly or indirectly can interfere with testing, including many agents used in the management of PPGL. These are summarized in Table 4. Increased sympathetic activity due to exercise or illness may also result in false positive results [110, 122, 123]. Diets rich in catecholamines may cause elevations in plasma and urine levels of 3-methoxytyramine, and fractionated urine metanephrines also [124].

When PPGL is suspected, CT with contrast is recommended as the initial imaging modality [105]. The abdomen and pelvis are usually imaged first, given this is where most tumors are located. MRI has a similar sensitivity and specificity to CT, and is also useful for detecting base of skull and neck paragangliomas [125]. Nuclear medicine studies are required in the presence of an SDHB mutation, pheochromocytoma >5 cm, or paraganglioma [126]. 123-MIBG is commonly used, but its sensitivity is less in SDHB associated tumors and paragangliomas [127]. In these instances ^{18}F-fluorodopamine (^{18}F-FDA), ^{18}F-fluorodihydroxyphenylalanine (^{18}F-FDOPA), and ^{18}F- fluoro-2-deoxy-D-glucose (^{18}F-FDG) are alternatives [128].[7] As with biochemical testing for PPGL, many drugs including commonly used antihypertensive agents interfere with testing, including alpha and beta blockers, and calcium channel blockers [129, 130]. Since up to 80% of children with PPGL will have an underlying mutation identified [105, 131], genetic testing should be performed concurrently with the biochemical and imaging workup.

Endocrine Disorders

Many endocrine disorders may cause HTN. Cushing syndrome is one differential diagnosis, commonly considered in the obese child with HTN. Key differences seen in Cushing syndrome compared to most HTN in obesity are a loss of linear growth and pubertal delay. Other features of glucocorticoid excess may be present such as a round face, increased fat at the base of the neck, striae, bruising, and proximal myopathy. Recommended first-line investigations for suspected Cushing syndrome include the low-dose dexamethasone suppression test, 24-h free urinary cortisol, and late-night salivary cortisol [132–134]. Either cortisol test should be performed twice to minimize the impact of day-to-day variation.

Table 4 Drugs that may impact metanephrine or catecholamine levels

	Plasma metanephrines	Plasma catecholamines	Urine metanephrines	Urine catecholamines
Beta-blockers	↑ M	°Δ	↑ NM/M	↑ NE/E
CCB	°Δ	↑ NE	°Δ	↑ NE/E
Phenoxybenzamine	↑ NM	↑ NE	↑ NM	–
Selective α-blockers	°Δ	°Δ	°Δ	↑ NE
Clonidine	↓ NM	↓ NE/E	–	–
Stimulants	↑ NM/M	–	↑ NM/M	–
Acetaminophen[a]	↑ NM	°Δ	↑ NM/M	↑ E

Selective serotonin reuptake inhibitors, tricyclic antidepressants, monoamine oxidase inhibitors, and levodopa may also impact metanephrine and catecholamine levels

Children with signs or symptoms of thyroid disease should have a thyroid stimulating hormone (TSH) level checked as a screen. Many obese children have slight elevations of TSH, yet many children with abnormal thyroid function tests do not have HTN [135, 136]. Elevations of TSH in many of these children will be normal on repeat testing, and/or will normalize with weight loss.

Several other important endocrine diagnoses can present with HTN. Adrenal adenomas are rare in children, but can occur in the context of specific calcium (CACNA1D) and potassium channel mutations (KCNJ5), described with neuromuscular abnormalities and a strong family history of HTN, respectively [137, 138]. While growth hormone excess (gigantism or acromegaly) is overall a rare condition, it is commonly associated with HTN and should be considered in the presence of coarse facial features, rapid height gain, and acral enlargement [139, 140]. HTN can be seen with hypercalcemia due to primary hyperparathyroidism, hypervitaminosis D, and in the setting of cancer with or without direct bone involvement [141, 142].

Other Causes of Secondary Hypertension in Children

Among infants, chronic lung disease appears to be a common cause of secondary HTN. Many of these children have other risk factors, including prematurity, umbilical artery catherization, and previous acute kidney injury [143, 144]. With improving outcomes among extremely premature babies the importance of preventing future CV events is likely to grow [145].

Intraventricular hemorrhage in the neonatal period is also associated with HTN [146]. In older children other intracranial events, including raised intracranial pressure and seizures, can produce HTN by altering autonomic output. Hence, in children with neurologic findings, brain imaging is required to rule out a space occupying lesion. Similarly, an electroencephalogram may be indicated where there is concern about undetected seizure activity. Peripheral autonomic dysfunction, for example with Guillain-Barre syndrome, may cause HTN also [147].

Several causes of HTN among children with cancer have been discussed, including fluid overload, PPGL, hypercalcemia, and kidney disease. In addition to PPGL, other tumors such as neuroblastoma may secrete catecholamines. As for PPGL, when testing for neuroblastoma, plasma 3-methoxytyramine may be a better measure of dopamine production, and normetanephrine of other catecholamine excess; elevated plasma 3-methoxytyramine or normetanephrine having a sensitivity of 98% compared to 90% for elevated urine dopamine, VMA, or HVA for neuroblastoma ([148], Pietzsch et al. 2020). Renin-secreting tumors are a rare but well described cause of HTN. These include some Wilms and renal cell carcinomas, or juxtaglomerular cells tumors, which may require cross sectional imaging for detection [149]. Extrinsic compression of the renal artery by abdominal masses and renal vein thromboses are not uncommon in the setting of childhood cancer.

Heavy metals, for example with lead or mercury, may cause HTN and be considered for testing where there is a high community prevalence or clinical suspicion of toxicity [150, 151].

End-Organ Damage and Stratifying the Risk of Downstream Sequelae

The ultimate goal of HTN management is to prevent progression to downstream events. While data linking HTN in early childhood to CV events are limited, studies across multiple populations have observed an association between HTN in adolescence and clinical outcomes, including mortality, CV events, stroke, and end-stage kidney disease [152–154]. With this in mind, it is important to evaluate other components of cardiometabolic and kidney risk simultaneously with BP.

Metabolic syndrome (MetS), the concurrence of dyslipidemia, impaired glucose tolerance, central obesity, and HTN, confers a substantial increase in long-term cardiovascular risk [155]. Elevated childhood BP has been linked to development of MetS in adulthood in longitudinal cohort studies [156], underscoring the long-term implications of high childhood BP. From a life-course perspective, while individuals with such clusters of risk factors are primed to develop disease due to genetic predisposition and early life exposures, trajectories can be altered by intervention prior to the development of established end-organ disease [157].

At the time of evaluating a child or adolescent with HTN, however, interest is usually focused on identifying more proximate effects of HTN such as LVH. Echocardiography is recommended for assessment of LVH in current pediatric guidelines given that electrocardiography has a low sensitivity for detection of LVH in childhood [158]. LVH is common among children with HTN, being present in 15–30%, and is correlated with systolic BP load [159, 160]. There are some differences between guidelines, but the indexation of left ventricular mass index (LVMI) to an exponent of height is standard, as this value is not age dependent [161]. Values of 38.6–51 $g/m^{2.7}$ have been proposed to define LVH, a level associated with an increased risk of CV events among young adults and greater than the 95th centile among healthy children [162, 163]. When present, serial measurements are useful to guide treatment response. LVMI is correlated with BP improvements while taking antihypertensive therapy, with a reduction in LVMI after commencing antihypertensive therapy best described among children receiving angiotensin converting enzyme inhibitors (ACEI) [164–166].

Although research studies have identified a link between high childhood BP and narrower retinal vessels [167], it is likely that development of clinically detectable hypertensive retinopathy is relatively uncommon among children [168]. Therefore, routine referral for formal ophthalmology review in most children and adolescents with HTN is not required. However, retinal abnormalities are more common among children presenting with hypertensive crises, and these may result in permanent loss of vision [169]. Hence, ophthalmology review is still recommended for children presenting with severe HTN or visual symptoms.

The use of carotid intima-media thickness (cIMT) and pulse wave velocity (PWV) to measure vascular structure and function is appealing as a method of determining intermediate vascular phenotypes on the pathway to CV disease in later life.

[170]. Both CIMT and PWV correlate with outcomes among adults, including CV events and chronic kidney disease (CKD) progression [171, 172]. As for LVMI, there remains debate about the clinical impact of modest improvements in risk prediction for these tests above that of routinely measured biomarkers [173]. These and other vascular markers, such as flow-mediated dilatation and augmentation index, remain primarily research tools for the time being. Albuminuria also currently falls into this category. Although it is an attractive biomarker and an independent predictor of risk in other populations, both as a measure of kidney disease and vascular dysfunction [68], data among hypertensive children are limited, and the clinical utility of any additional quantification is unclear [174].

Therapy of Hypertension

Non-pharmacologic

Comprehensive lifestyle changes addressed at reducing factors responsible for high BP are recommended as initial actions to control high BP in children and adolescents [4–6]. Considerable advances have been made in recent years in identifying the main condition associated with and considered responsible for high BP in children and adolescents, overweight and obesity [1]. More limited evidence, albeit limited, has been compiled on the results of corrective interventions. Therefore, at present the most recommended approach to the treatment, of obesity-associated HTN consists of weight reduction through achieving a healthy lifestyle, characterized by eating healthy, performing physical activity, avoiding sedentary behaviors, and obtaining good quality sleep. Currently this treatment's approaches lead to positive outcomes only in patients where there is an adherence to intervention that is maintained over time.

Unfortunately, these recommendations are often difficult to achieve, especially for adolescents. In order to achieve these objectives among this population, the goals need to be established realistically, tailored to individual and family characteristics, involving the family as partners in the behavioral change process, providing educational support and materials [4–6]. Motivational interviewing approaches have been shown to be effective in achieving weight loss in the clinical trial setting [175, 176] and should be considered when treating children and adolescents with overweight and obesity.

There is no doubt about the health benefits associated with regular physical activity in children and adolescents. It has been demonstrated that regular physical activity has cardiovascular benefits. In fact, in a recent meta-analysis conducted in adults it has been established that physical activity reduced BP among adults with normal BP, prehypertension, and HTN [177]. In pre-pubertal obese children regular physical activity training for 60 min 3 times/week over 3 months resulted in a significant reduction of BP, not only when measured in the office, but also when monitored for 24-h BP. Higher levels of physical activity are associated with lower BP and results suggested that the volume of activity might be more important than the intensity [178]. The World Health Organization recommends at least 60 min daily of moderate- to vigorous-intensity physical activity [179]. Recent Guidelines on Physical Activity published by the US Department of Health and Human Services are consistent with the World Health Organization, and emphasized vigorous-intensity physical activity at least 3 days a week. Although children under 5 years of age benefit from being active, more research is needed to determine what dose of physical activity provides the greatest health benefits [180].

To better plan physical exercise, an evaluation of cardiorespiratory fitness may provide useful information. Physical fitness represents an integrated measure of all the functions and structures, musculoskeletal, cardiorespiratory, hematocirculatory, endocrinometabolic, and psychoneurological functions, involved in the practice of physical activity or exercise. In children and adolescents, despite the scarce number of studies, strong associations with cardiometabolic abnormalities have been described [181, 182] and should be taken into consideration for developing effective and personalized interventions. Strong evidence indicates that performing moderate-to-vigorous physical activity, particularly aerobic exercise, and improving cardiorespiratory fitness reduce BP levels and the incidence of HTN. Consequently, to lower the risk of HTN, promoting physical activity and improving fitness, especially cardiorespiratory fitness, should be encouraged [183].

Prospective studies have shown the effects of diet on lifetime BP. Consumption of >1 servings of dairy products/day and >2 servings of fruits and vegetables/day throughout adolescence has shown to lead to about a 35% lower risk of elevated BP [184]. However, children's vegetable consumption is generally below recommended levels. Therefore, future research should investigate ways to encourage vegetable intake at times when vegetables are not regularly eaten, such as for breakfast and as snacks, while considering which other, potentially competing, foods are presented alongside vegetables.

There are other considerations that need to be taken into account for overall prevention of HTN. For example, a reduced saturated fat–diet from infancy decreases BP [185] and the association of higher sugar sweetened beverage consumption with higher systolic BP in adolescents [186]. High salt intake in children and adolescents is positively correlated with high systolic BP and an elevated risk of HTN [187] and a meta-analysis has shown that a 3 g/day reduction of salt intake leads to a decrease in SBP and DBP of 1.2/1.3 mmHg [188]. Starting in newborns, a 15-year follow-up study has suggested a predictive role of the effect of salt intake in early life on BP [189]. Excessive salt intake seems to be not only linked with BP elevation but also to other cardiovascular risk factors since salt produces a reduction in vascular nitric oxide bioavailability that limits endothelium-dependent dilation [190].

In addition to the dietary factors outlined above, there are other non-pharmacologic measures that merit consideration. The relevance of tobacco smoking has been widely demonstrated. Even after correction for other risk factors, such as body mass index, parental HTN, or birth weight, parental smoking independently affected systolic BP in preschool children [191]. Implementing a smoke-free environment at home and in public places may provide a long-term cardiovascular benefit even to young children, and may even help to prevent the uptake of cigarettes in adolescents. Yoga and other stress reduction techniques have shown promise in reducing BP in some studies [192, 193].

Lifestyle interventions are important because they can delay the need for drug treatment or complement the BP lowering effect of antihypertensive treatment. Application of the Dietary Approaches to Stopping Hypertension diet in adolescents with high BP reduced BP and improved endothelial function [194]. Aside from the condition's associated with overweight and obesity, non-pharmacological treatment should be considered as an accompanying measure to drug treatment in secondary form of HTN. Moreover, lifestyle interventions such as regular exercise, healthy eating, weight control, sodium restriction, and smoking cessation all have health benefits beyond their impact on BP.

Pharmacologic Therapy

Lifestyle measures do not result in immediate reduction of BP, and may not reduce BP sufficiently in children and adolescents with HTN at or above stage 2. Additionally, there may be other considerations such as the presence of underlying conditions, symptoms, or hypertensive target-organ damage, which may justify starting an antihypertensive medication at the time of or shortly after diagnosis. Indications from current pediatric HTN guidelines [4–6] for initiating antihypertensive medications are summarized in Table 5.

Choice of initial medication is often confusing. While some experts recommend using a pathophysiologic approach to the use of antihypertensive medications in children and adolescents, in general the choice of agent is left up to the individual prescriber. Consideration should be given to special conditions such as underlying CKD or diabetes, or the concurrent presence of migraine headache when choosing a medication, similar to the "compelling indications" approach recommended in the past for adults. Some medications may be contraindicated in special circumstances, such as angiotensin converting enzyme inhibitors (ACEI) in patients with bilateral renal artery stenosis [5, 6]. Additionally, if the child or adolescent is found to have a monogenic form of HTN there is often a specific agent that will target the mechanism of the HTN. These and other considerations have been discussed in detail elsewhere [195].

Table 5 Indications for antihypertensive drug treatment

Primary Hypertension
Failure to respond to lifestyle modification Stage 2 hypertension without an easily modifiable contributing factor Symptomatic hypertension
Underlying high-risk conditions
Chronic kidney disease Type 1 and type 2 diabetes Known hypertensive target-organ damage Repaired coarctation of the aorta Other secondary forms of hypertension
Monogenic Hypertension

Ref: Flynn et al [4], Lurbe et al [5].

First-line antihypertensive agents recommended by the AAP include long-acting calcium channel blockers, ACEI, angiotensin receptor blockers (ARB), and thiazide diuretics [4]. The ESH guideline cautions against use of thiazide diuretics as initial therapy because of their potential adverse effects on glucose metabolism [5, 6]. Other classes of agents including beta- and alpha-adrenergic blockers are generally reserved for second- or third-line use given their known side effects. Monotherapy with long-acting drugs that can be dosed once daily is preferred, but additional agents may be needed to achieve optimal BP levels (see below).

Historically, drugs prescribed for children were not studied rigorously to assess for efficacy, safety, or appropriate dosing regimens. The passage of the Federal Drug Administration (FDA) Modernization Act in 1997 heralded an era of increased rigor with respect to pediatric drug development by providing financial incentives to industry sponsors for conducting pharmaceutical trials in children [196]. Subsequent legislative efforts, including new pediatric drug regulations in Europe [197], have facilitated ongoing attention to this area. Antihypertensive drugs represent one of the largest groups of medications impacted by these efforts [198]. Consequently, a growing number of antihypertensive medications from different classes have been studied in children and adolescents, resulting in more of these agents receiving FDA-approved labeling for use in children and adolescents [199]. Many of the antihypertensive medication-related recommendations in the AAP and ESH guidelines are based on the information derived from those trials.

Antihypertensive drugs in children and adolescents are generally prescribed in a stepped-care manner: The child is initially started on the lowest recommended dose, then the dose is increased until the highest recommended dose is reached, or until the child experiences adverse effects from the medication, at which point a second drug from a different class should be added, and so on, until the desired goal BP is reached. Pediatric dosing recommendations for selected antihypertensive medications can be found in Table 6.

Recommended treatment targets for children and adolescents with HTN have evolved over time as new data have become available on optimal BP levels. For example, the AAP guideline adopted a lower general treatment goal, office BP below the 90th percentile, for all children and adolescents than in prior US guidelines largely because of new adult data demonstrating that lower BP has a beneficial effect on long-term outcomes [4]. The ESH pediatric guideline maintained a general office BP goal of the 95th percentile for children and adolescents with primary HTN, but the same goal for children and

Table 6 Selected medications for oral therapy of childhood hypertension[a]

Class	Drug	Dosing[b]
Alpha adrenergic blockers	Prazosin Doxazosin	0.05–0.1 mg/kg/day divided TID; Max: 0.5 mg/kg/day 0.5–1.0 mg/day; Max 16 mg/day
Angiotensin receptor blockers	Candesartan Losartan[a] Olmesartan Valsartan	Start: 0.2 mg/kg/day up to 8 mg/day; Max: 0.4 mg/kg/day up to 32 mg/day (32 mg) Start: 0.7 mg/kg/day divided BID; Max: 1.4 mg/kg/day divided BID; (100 mg) Start: 10–20 mg/day; Max: 20–40 mg/day (40 mg) Start: 1.3 mg/kg/day up to 40 mg/day; Max: 2.7 mg/kg/day up to 160 mg/day (320 mg)
Angiotensin converting enzyme inhibitors	Enalapril Lisinopril[c] Ramipril	Start: 0.08 mg/kg/day divided BID; Max: 0.6 mg/kg/day divided BID (40 mg) Start: 0.07 mg/kg/day; Max: 0.6 mg/kg/day (40 mg) 1.25–2.5 mg/day; Max: 20 mg/day (ESCAPE trial used 6 mg/m^2/day)
Beta-adrenergic blockers	Atenolol Propranolol[c] Metoprolol Succinate	Start: 0.5 mg/kg/day divided BID; Max: 2 mg/kg/day divided BID (100 mg) Start: 1 mg/kg/day divided BID; Max: 8 mg/kg/day (640 mg) Start: 1 mg/kg/day up to 50 mg; Max: 2 mg/kg/day up to 200 mg (200 mg)
Calcium channel blockers	Amlodipine[c] Extended-release nifedipine	Start: 0.1 mg/kg/day; Max: 0.6 mg/kg/day (10 mg) Start: 0.2 mg/kg/day; Max: 3 mg/kg/day (120 mg)
Mineralocorticoid Receptor antagonists	Eplerenone Spironolactone	25 mg/day; Max 100 mg/day 1 mg/kg/day; Max: 3.3 mg/kg/day (100 mg)
Thiazide diuretics	Hydrochlorothiazide Chlorthalidone	Start: 1 mg/kg/day; Max: 2 mg/kg/day (50 mg) Start: 0.3 mg/kg/day; Max: 2 mg/kg/day (50 mg)

BID twice-daily, *d* day, *kg* kilogram, *mg* milligram

[a] Starting and maximal doses given either as absolute dose or as weight-based ranges. Maximum adult dose in parentheses. Always consult updated pediatric prescribing information

[b] All drugs can be administered once-daily except as otherwise indicated

[c] Suspension preparations commercially available

adolescents with secondary HTN as in the AAP guideline [5, 6]. Both organizations recommend using an ABPM-based goal for children with CKD based on data from the ESCAPE trial showing that that strict BP control, defined as 24-h mean arterial pressure (MAP) below the 50th percentile leads to improved long-term renal survival [37].

Once medication treatment has been initiated, it is important to ensure that BP goals are reached and maintained. Children and adolescents treated with lifestyle measures only should be seen every 3–6 months to monitor the effect of treatment and to encourage continued adherence. Those started on antihypertensive medications should be seen frequently at first, perhaps every 6–8 weeks, so that drugs can be titrated, and then less often once a stable regimen and the goal BP attained. HBPM is a useful tool to help determine response to medication treatment. Repeat ABPM may also be used, and is mandatory in children and adolescents with HTN, specifically those with CKD to monitor the 24-h MAP and ensure that the targets based on data from the ESCAPE trial are being met [4–6]. Finally, children treated with specific medication classes – ACEI, ARBs and diuretics – require periodic laboratory monitoring to assess for electrolyte disturbances and other medication-related toxicities, and those with known target-organ effects such as LVH should undergo periodic reassessments as indicated.

Acute Severe Hypertension

Acute severe HTN, defined as significant BP elevation with or without evidence of acute hypertensive target organ damage, requires prompt therapy to prevent and/or ameliorate further target organ damage. Traditionally the terms hypertensive urgency and hypertensive emergency have been used to describe this condition, but since the distinction between these is arbitrary, we prefer the term “acute severe HTN.”

The most common causes of acute severe HTN in children and adolescents are summarized in Table 7. While some patients may have no identifiable cause, the majority of affected patients have secondary causes of HTN [200]. Mechanisms of acute severe HTN may include volume overload with or without renal dysfunction, and/or activation of the renin-angiotensin-aldosterone system. Etiology and pathophysiology have been discussed in more detail elsewhere [201, 202]. While a variety of organs may be affected in patients with acute severe HTN, the central nervous system is the most commonly affected target organ.

Treatment of acute severe HTN requires continuous monitoring of BP and meticulous patient monitoring to prevent excessively rapid lowering of BP. In patients with the most significant target organ involvement, BP should be lowered no more than 25% of the planned reduction over the first 8 h to prevent compromise of organ perfusion (e.g., cerebral, coronary, or renal ischemia). The ultimate BP target in the acute phase is usually the 95th percentile, and can be achieved over the next 24–48 h [201, 202]. In most patients, this will require administration of intravenous antihypertensive medication(s), most commonly labetalol or nicardipine. In less severely affected patients, oral medications may be considered. Drug dosing for patients with acute severe HTN has been described in detail elsewhere [203]; suggested drug doses are presented in Table 8.

Pheochromocytoma and Paraganglioma

Many children with pheochromocytomas initially present acutely with severe, symptomatic HTN of unknown etiology [105]. Such children require careful immediate stabilization and gradual BP reduction as described in below until the diagnosis is made. Although theoretically the α- and β-adrenergic blocker labetalol may seem uniquely well-suited for treatment of HTN caused by a pheochromocytoma, in practice a continuous infusion of any of the intravenous antihypertensives listed in Table 8 could be utilized for initial BP management. Phentolamine has also been advocated in such patients, although pediatric experience with this agent is limited.

Once the diagnosis of pheochromocytoma has been made, the child’s BP should be stabilized

Table 7 Causes of acute severe hypertension in children and adolescents

Kidney Disease	**Malignancies**
Acute glomerulonephritis Reflux nephropathy Acute kidney injury Polycystic kidney disease Hemolytic-uremic syndrome End-stage kidney disease at presentation	Pheochromocytoma Wilms tumor Neuroblastoma
Vascular	**Other**
Aortic coarctation (thoracic, abdominal) Renal artery stenosis Vasculitis (Takayasu's, Polyarteritis nodosa, others)	Medication noncompliance in a patient with known hypertension Drug-induced, especially abrupt withdrawal of clonidine or beta-blockers Primary hypertension (unusual)

Table 8 Recommended antihypertensive medications for acute severe hypertension

Useful for severely hypertensive patients with life-threatening symptoms				
Drug	**Class**	**Dose**	**Route**	**Comments**
Esmolol	β-adrenergic blocker	100–500 mcg/kg/min	iv infusion	Very short-acting—constant infusion preferred. May cause profound bradycardia
Hydralazine	Direct vasodilator	0-1-0.2 mg/kg/dose up to 0.6 mg/kg/dose	iv, im	Should be given q 4 h when given iv bolus
Labetalol	α- and β-adrenergic blocker	bolus: 0.20–1.0 mg/kg/dose, up to 40 mg/dose infusion: 0.25–3.0 mg/kg/h	iv bolus or infusion	Asthma and overt heart failure are relative contraindications
Nicardipine	Calcium channel blocker	bolus: 30 mcg/kg up to 2 mg/dose infusion: 0.5–4 mcg/kg/min	iv bolus or infusion	May cause reflex tachycardia. Increases cyclosporine and tacolimus levels
Sodium nitroprusside	Direct vasodilator	Starting: 0-3-0.5–10 mcg/kg/min Maximum: 10 mcg/kg/min	iv infusion	Monitor cyanide levels with prolonged (>72 h) use or in renal failure; or co-administer with sodium thiosulfate
Useful for severely hypertensive patients with less significant symptoms				
Drug	**Class**	**Dose**	**Route**	**Comments**
Clonidine	Central α-agonist	2–5 mcg/kg/dose, up to 10 mcg/kg/dose given Q6–8 h	po	Side effects include dry mouth and drowsiness
Fenoldopam	Dopamine receptor agonist	0.2–0.5 mcg/kg/min up to 0.8 mcg/kg/min	iv infusion	Higher doses worsen tachycardia without further reducing BP
Hydralazine	Direct vasodilator	0.25 mg/kg/dose up to 25 mg/dose given Q6–8 h	PO	Half-life varies with genetically determined acetylation rates
Isradipine	Calcium channel blocker	0.05–0.1 mg/kg/dose up to 5 mg/dose given Q6–8 h	po	Exaggerated fall in BP can be seen in patients receiving azole antifungals
Minoxidil	Direct vasodilator	0.1–0.2 mg/kg/dose up to 10 mg/dose given Q8–12 h	po	Most potent oral vasodilator; long-acting

ACE angiotensin-converting enzyme, *BP* blood pressure, *IM* intramuscular, *IV* intravenous, *kg* kilogram, *mcg* microgram, *mg* milligram, *PO* oral with oral antihypertensives until the tumor can be surgically removed. Phenoxybenzamine, a potent α-adrenergic blocker, is usually recommended as the primary agent for this phase of management, although there has been a recent trend toward use of the peripheral α-adrenergic antagonist doxazosin for α-blockade [204, 205]. β-adrenergic blockade may be needed as adjunctive therapy to counter tachycardia once full α-blockade has been reached, especially in patients treated with phenoxybenzamine. Other important aspects of preoperative treatment include volume expansion and salt-loading; patients are typically admitted for 24–48 h prior to surgery to accomplish this. Patients who remain hypertensive postoperatively may require a short period of oral antihypertensive therapy; any agent is suitable in such cases. Patients with metastatic disease may require long-term antihypertensive therapy with either phenoxybenzamine or doxazosin.

Unanswered Questions/Research Needs

Despite the advances and the extensive literature on BP in children and adolescents, answers to relevant questions are still pending. The accurate measurement of BP is a prerequisite for the reliable diagnosis of HTN. Although automated electronic devices are currently recommended and widely used, the published evidence on their accuracy in children and adolescents is limited. Validated devices for oscillometric BP measurement should be developed, and inclusion of children in device validation studies should be encouraged. Concerted action of healthcare professionals, consensus organizations, industry, and society at large is needed for better identification of high BP identification and treatment among children and adolescents.

Robust reference values for office, ambulatory, and home BP, ideally including children and adolescents of multiple ethnic groups, need to be developed and matched with better knowledge about the development and progression of early organ damage. It is necessary to refine the clinical significance of white-coat HTN and masked HTN due to the discrepancies between office and out-off office BP. A better knowledge of all of these aspects may contribute to optimized interventions, preventing organ damage and improving long-term prognosis. Additional steps forward would be to obtain insights on central BP and pulse wave velocity as markers of function of the vascular system. Better understanding of isolated systolic HTN and its management is important in order to comprehend its significance and potential impact.

Preventive and treatment measures, such as healthy nutrition, low salt intake, nonsmoking, alcohol avoidance, and exercise activity, need to be encouraged. Clinical trials with antihypertensive drugs in order to gain knowledge about specific benefits and disadvantages of BP lowering agents and establish adequate doses should be designed and performed. Implementing electronic health technologies such as remote BP monitoring [206] will provide tools to improve attainment of BP targets and encourage adherence to prescribed therapies. Recognizing that the antecedents of adult HTN and its sequelae begin in childhood, the ultimate goal of all these efforts should be aimed at improvement in the long-term cardiovascular health of all individuals.

Abstract

Renal artery stenosis is an unusual but important cause of high blood pressure (BP) in children. It often presents with very severely raised BP and symptoms of target organ damage. The cause is unknown in most cases, but fibromuscular dysplasia and Takayasu arteritis are the most common depending on the child's

geographic location. A minority of cases are related to syndromes, mainly Neurofibromatosis type 1 and Williams syndrome. Ultrasound and CT angiography are used in the initial investigation, but digital subtraction angiography is the gold standard investigation. Medical treatment rarely achieves adequate BP control, and the most commonly used treatment is angioplasty. Vascular surgery such as arterial bypass or autotransplantation of the kidneys is used in a significant minority of children. Outcomes of angioplasty, including restoration of renal blood flow and improvement of BP, are good in the majority of children, but there is a significant minority where current treatment options are ineffective in achieving a sustained BP control and preventing end organ damage.

Introduction

In the majority of cases, hypertension (HT) is defined as primary, in the present-day situation of screening and the obesity epidemic. Of the secondary cases of HT, 5–10% are caused by renal artery stenosis (RAS). This chapter describes the etiology, investigations, treatment, and outcome of children with RAS.

Clinical Presentation

Renovascular hypertension (RVH) is diagnosed as an incidental finding in 27–54% of cases, with a higher frequency of incidental presentation in countries where blood pressure (BP) screening in children and adolescents is mandatory. RVH usually presents as severe hypertension, often fulfilling the criteria for the definition of hypertensive crisis. It is common in all age groups [1, 2]. Syndromic forms of RVH are accompanied by signs and symptoms typical for each clinical syndrome.

The clinical presentation of RVH is often nonspecific and may manifest as fatigue, reduced exercise capacity, or signs and symptoms directly associated with hypertensive crisis. Younger children usually do not complain of any symptoms or may present with nonspecific symptoms such as loss of appetite and failure to thrive [2, 3]. In some young children, the first presentation may be with signs of end organ damage and hypertensive crisis such as seizures, stroke, heart failure, lethargy, or failure to thrive. In contrast, older children more often present with a wide spectrum of neurological and cardiac signs and symptoms. Headache is the most commonly reported symptom and was recorded in 17–37% of patients [1, 2, 4–6]. In 18% of cases, headaches were accompanied by other symptoms, such as fatigue, vomiting and/or lethargy, and excessive screaming in younger children, which may be indicative of brain edema. Other neurological symptoms at presentation include seizures, eye ptosis, facial nerve palsy (7.7%), and stroke (subarachnoid, intracerebral, or ischemic; 3.9%). Ischemic stroke may be the first clinical symptom of neurovascular involvement of the external or internal cerebral arteries or of moyamoya disease which may be accompanied by renal artery stenosis. Other symptoms were epistaxis (5%), and in cases of unilateral renal artery stenosis hyponatremic hypertensive syndrome (HHS) with pressure natriuresis and polyuria (1–4%). Pulmonary edema was reported in children with bilateral renal artery stenosis [7]. Abdominal bruit was found in 10% of children. Cervical bruits were detected in 5.7% of children with RVH caused by fibromuscular dysplasia (FMD) [8] (Table 1).

Laboratory findings may indicate secondary hyperaldosteronism, especially in cases caused by unilateral renal artery stenosis (RAS), and may typically include hypokalemia with metabolic alkalosis. Urinalysis may reveal acidic urine. Plasma renin activity/renin concentrations and aldosterone levels are typically high; however, in cases of bilateral renal artery stenosis, renin generation and hyperaldosteronism may not be as strongly expressed due to sodium retention. Hyponatremia may be observed in cases of HHS with severe hypertension and pressure natriuresis. In unilateral renal artery stenosis, hypertensive injury to the contralateral kidney that is exposed to a high systemic BP may result in trace to severe proteinuria and red blood cells in the urine [9] (Table 1).

Features of hypertensive target organ damage are commonly found even at presentation. In reported series, left ventricular hypertrophy was noted in 56–67% of patients, and in 8% myocardial injury, manifesting as ischemia and/or rhythm disturbances, was observed [1]. Left ventricular hypertrophy was diagnosed more often in those who presented with clinical symptoms [1, 2, 10]. Subclinical arterial injury in the form of an increased carotid intima-media thickness was also commonly recognized, especially in cases with midaortic syndrome and renal artery stenosis [11]. Injury to the microcirculation manifesting as hypertensive arteriolopathy in the retina was found in 50–78% of patients [1, 10]. Narrowing of retinal arterioles (stage I) was detected in 47%, and arteriolar stiffening with venular compression (stage II) in 26.5% of patients. More severe forms of hypertensive retinopathy, namely stage III and IV, indicating damage to the microcirculatory barrier, were observed in 4.6% of cases [1].

Table 1 Presentation of renovascular hypertension in children

Presentation	%
Incidental finding or blood pressure screening	46–54%[a]
Headache	17–37%
Headache with vomiting, excessive screaming, and lethargy	11–23%
Heart murmur, congestive heart failure, and rhythm disturbances	8–10%
Hypertensive crisis (including seizures, Bell's palsy, ptosis, and stroke)	4–10%
Failure to thrive, weight loss	1–7%[b]
Epistaxis	4.5%
Symptoms caused by hypertensive injury to the kidney with patent renal artery:	
Proteinuria, hematuria	10%
Hyponatremic hypertensive syndrome	1–4%[b]

[a] More often in countries where blood pressure screening in childhood is mandatory

[b] More often in younger children, below 5 years

Etiology

The causes of renal artery stenosis (RAS) are several fold and presented in Table 2.

Fibromuscular Dysplasia

The underlying diagnoses causing RAS are not well defined in the majority of children, and in Europe and North America a majority of cases are given the diagnosis fibromuscular dysplasia (FMD) [2, 5, 7, 10, 12, 13]. This is a condition that can be diagnosed either from pathognomic "string of beads" patterns on renal angiography, or on histopathology [8]. Given that the majority of children with RAS are treated with angioplasty (see below), there is no opportunity to obtain a tissue sample for histological confirmation of the diagnosis.

Table 2 Causes of renovascular hypertension in children

Rubella syndrome
Transplant renal artery stenosis

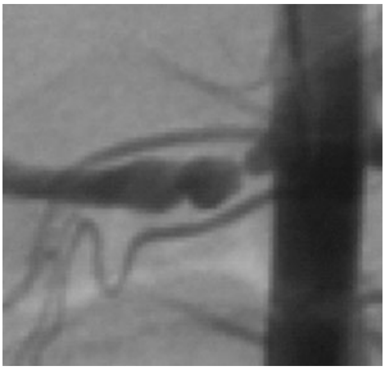

Fig. 1 Angiography in a child with renal artery stenosis due to fibromuscular dysplasia showing typical string of bead pattern

The string of beads pattern, Fig. 1, is a diagnostic feature in adult FMD but is only seen in a minority of cases in children, raising the question if adult and pediatric FMD are the same condition or not. FMD in children is thus mainly a diagnosis of exclusion without the possibility of confirming a positive diagnosis. Current classification of FMD used in adults distinguishes focal, multifocal, and multivessel lesions (Table 3); this has not been validated in children.

Syndromic RAS

A number of syndromes are associated with RAS. Of those, Neurofibromatosis type 1 and Williams syndrome are the two most common, accounting for 15–25% of cases in most published series [15]. Importantly, only a minority of children with these syndromes develop clinically overt RVH.

Takayasu Arteritis

Takayasu arteritis (TA) is the most common diagnosis given to children with RAS in Asia and Africa [16–19]. Takayasu arteritis is diagnosed with one obligatory criterion – an angiographic abnormality of the aorta or its main branches, plus at least one of the following four features: decreased peripheral artery pulses and/or claudication of extremities, BP difference between arm and leg of greater than 10 mmHg, bruits over the aorta and/or its major branches, hypertension, or a single value of ESR above 20 mm/h or CRP raised above normal range [20]. The authors emphasize that these are *classification criteria* thus indicating that a diagnosis of an inflammatory condition needs to be confirmed before using them. In many cases series of children with TA, more than half of the cases are diagnosed without any inflammation and the children are deemed to be in the late “burned out” phase [21]. It is unclear how the classification criteria can be used in these children.

Is It Fibromuscular Dysplasia or Takayasu Arteritis?

The differential diagnosis between FMD and TA remains unclear and controversial [15], and the reason for the difference in diagnostic patterns between countries is not fully known.

If we apply the criteria for FMD and TA, the vast majority of children in our renovascular clinics who do not have a clear syndrome or other specific etiology will fulfill the criteria for both conditions. This is obviously confusing and may lead to children not getting appropriate treatment. While it is very important that children with clear signs of an inflammatory vasculitis receive appropriate immunosuppression, it is also equally important that children without such symptoms and signs do not receive unnecessary treatment. Of note, appropriate anti-inflammatory treatment may not improve either the vascular lesions or the hypertension. Thus, in children with TA, when the vasculitis is under medical control, appropriate treatment of their vascular stenosis with either angioplasty or surgery is required.

Vascular Involvement

Renal artery stenosis can often be a condition involving many arterial beds. This seems to be the case regardless of the underlying etiology. Children can present with bilateral RAS in 53–78% of cases, midaortic syndrome in 48%, and stenoses of superior and inferior mesenteric

Table 3 Definition and classification of fibromuscuar dysplasia (FMD) according to First International Consensus on the diagnosis and treatment of fibromuscular dysplasia

Definition	FMD is an idiopathic, segmental, nonatherosclerotic, and noninflammatory disease of the musculature of arterial walls, leading to stenosis of small and medium-sized arteries. Histopathological classification is no longer clinically applicable. Current definition is based on radiographic criteria
Classification	FMD may result in two types of changes found on radiography: Focal FMD: May be found in any part of the artery Multifocal FMD: Areas of stenoses and dilation (string of beads) "Multivessel disease" is not included in the classification but is used in practice

Adapted from Ref. [14]

arteries in 53% [22]. Nevertheless, more frequent use of computed tomography angiography (CTA) in hypertensive children suspected of having RVH may lead to different results. However, more detailed, recent analysis of Assessment of Renal and Cervical Artery Dysplasia-Poland (ARCADIA-POL) Registry data has revealed that single-site FMD was found in 69.8%; 25% of participants, both adults and children with FMD, had cerebrovascular bed involvement, and 9.5% of them presented with visceral arterial involvement [23, 24]. Subanalyses of data from pediatric patients with FMD revealed that 29% of them presented with multivessel disease including visceral, carotid, and/or intracranial arteries (unpublished data). Due to the systemic nature of FMD, diagnostic imaging should also include other arterial beds besides the renal arteries. Although there are no specific pediatric recommendations for diagnostic imaging in children with FMD, recommendations for adults with FMD include the imaging of renal, visceral, cervical, and intracerebral arteries [14].

Aneurysmal Disease

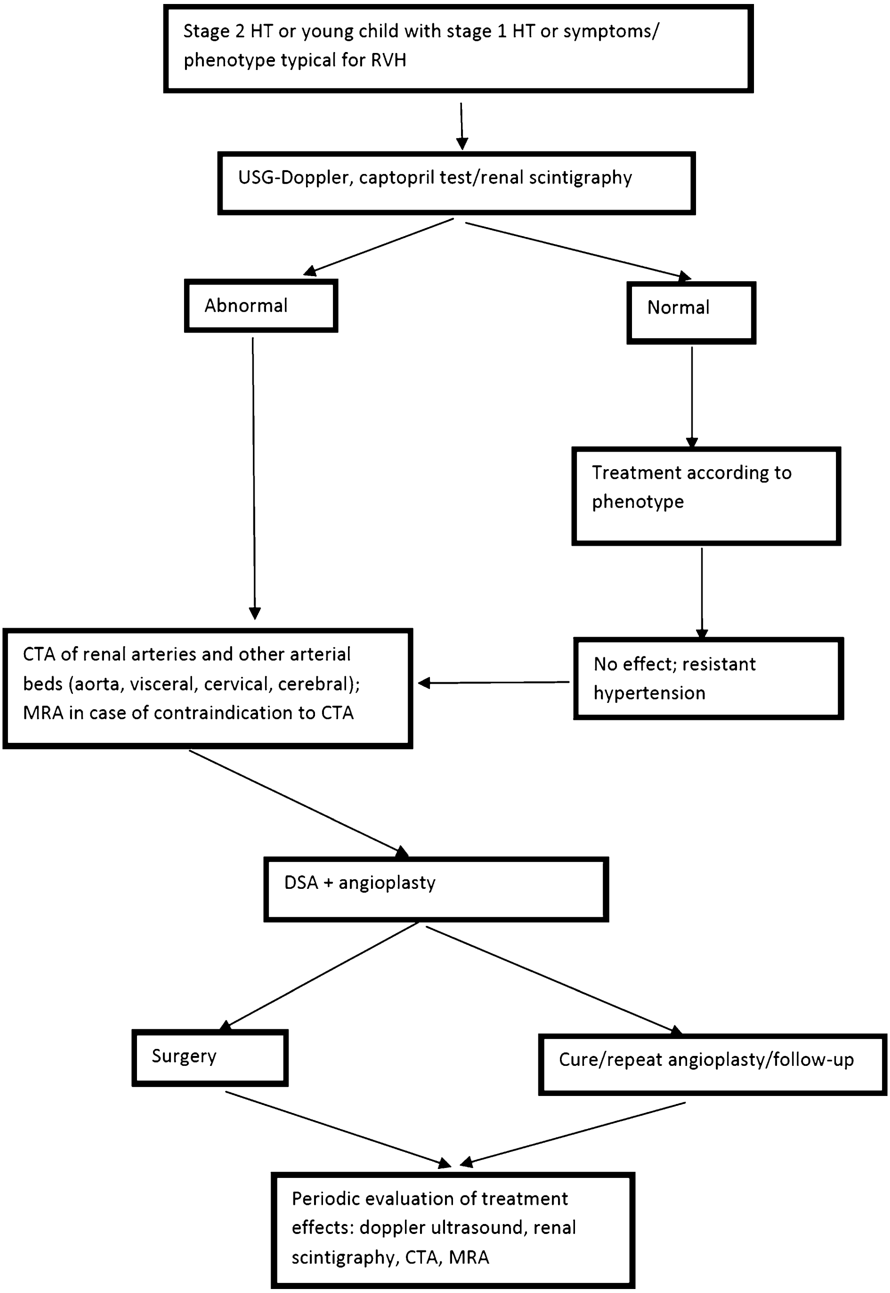
A small group of children with FMD show aneurysms both of the renal arteries and also other vascular beds including, the aorta and iliac arteries, at presentation. In a small group of children, aneurysms are the predominant problem without any stenotic lesions. In one study from Michigan, a total of 41 children with 61 aneurysms in a large number of different vascular beds were presented [25]. A significant minority of these patients had comorbidities that may be causative of the aneurysm such as trauma, Kawasaki disease, or Ehler Danlos type IV syndrome, while most of the patients seemed to belong to the same spectrum of conditions as FMD.

Diagnostic Imaging

Renal ultrasonography with Doppler flow measurements is the first-line imaging used for diagnosis of renal artery stenosis. It is generally believed that renal ultrasonography with Doppler flow measurements should be offered to all hypertensive children, younger children before puberty, and older children with stage 2 hypertension because of greater likelihood of secondary hypertension in younger children and in those with more severe hypertension [26]. The other noninvasive imaging procedures include renal scintigraphy, CTA, and magnetic resonance angiography (MRA) which are used as second-line diagnostic procedures. Angiography can be both diagnostic and therapeutic, with angioplasty performed during the same session. The extent of imaging procedures depends on the etiology of RVH and may also include other arterial regions such as the aorta and visceral arteries, as well as cervical and intracerebral arteries. A suggested diagnostic algorithm is shown in Fig. 2.

Ultrasound Imaging (Fig. 3)

There are two Doppler imaging techniques, namely direct and indirect method, which should preferably be used in conjunction for the evaluation of the renal arteries. The direct method is based on the assessment of flow in the renal artery. It is performed from the aorta to the renal hilum.



Stage 2 HT or young child with stage 1 HT or symptoms/ phenotype typical for RVH
USG-Doppler, captopril test/renal scintigraphy
Abnormal
Normal
Treatment according to phenotype
No effect; resistant hypertension
CTA of renal arteries and other arterial beds (aorta, visceral, cervical, cerebral); MRA in case of contraindication to CTA
DSA + angioplasty
Surgery
Cure/repeat angioplasty/follow-up
Periodic evaluation of treatment effects: doppler ultrasound, renal scintigraphy, CTA, MRA

Fig. 2 Scheme of diagnostic and management approach in children with renovascular hypertension. (Based on Refs. [22, 27])

The following parameters suggest hemodynamically significant renal artery stenosis:

- Peak systolic velocity (PSV) in the renal artery >180–200 cm/sec.
- Renal-aortic ratio (RAR = renal artery PSV/aortic PSV) >2–3.5.
- Renal-interlobar ratio (RIR = renal artery PSV/interlobar PSV) >5.

The indirect method is based on the assessment of the arterial flow in the renal parenchyma (either in the interlobar or arcuate arteries), with

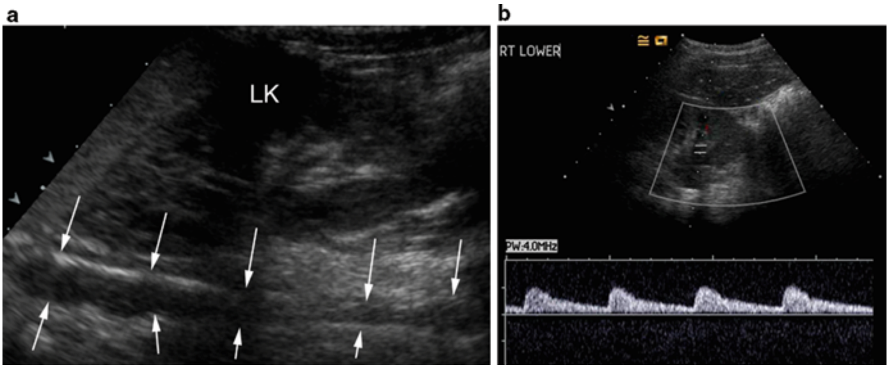


Fig. 3 Ultrasound showing. (**a**) midaortic syndrome (**b**) *parvus and tardus* flow pattern on Doppler imaging

the following abnormalities that may indicate renal artery stenosis:

- Presence of a *tardus et parvus* (slow and small) waveform (Fig. 3).
- Renal arterial resistive index (RI) <0.55.
- Difference between right and left kidney RI values $>5\%$.
- Acceleration time >70–80 milliseconds.
- Acceleration index (AI) <3 m/s^2.

Besides flow analysis, direct visualization of arterial stenosis or a significant (≥ 1 cm) difference in kidney length may suggest renovascular disease [28, 29].

Sonographic assessment of renal arteries is cheap, easily available, radiation free, and highly specific (94–99%). However, given that it is operator-dependent, and that the imaging quality may be affected by a lack of patient cooperation, it is characterized by low sensitivity (63–65%) for the detection of RAS. The sensitivity of ultrasonography in diagnosis of RVH can increase to 73% when kidney length is added to the analysis [29, 30]; however, its value is lower in case of peripheral, segmental branch stenosis [31].

Renal Scintigraphy

Renal scintigraphy, both static and dynamic, enables the assessment of tracer uptake and differential renal function. Scintigraphy captopril test is used to assess renal tracer uptake, after angiotensin-converting enzyme (ACE) inhibition, and may reveal abnormal blood flow to a kidney with a stenosed renal artery or its branches. Static renal scintigraphy with ^{99}technetium labeled dimercaptosuccinic acid (DMSA) shows only differential renal tracer uptake or its change after ACE inhibition. In contrast, dynamic renal scintigraphy with ^{99}technetium labeled mercaptoacetyl triglycine (MAG3) gives insight into blood flow to the kidneys, as well as into the velocity of intrarenal clearance and excretion. There is limited pediatric data showing that renal scintigraphy has a low sensitivity (48–86%) and specificity (73–92%). Therefore, renal scintigraphy is not recommended as a diagnostic test for RAS in children [26, 32, 33]. However, despite the above-mentioned limitations, this procedure is a useful tool in both the assessment of pre- and postintervention renal blood flow, as well as to define the differential renal function before intervention and at follow-up (Fig. 4a, b).

Magnetic Resonance Angiography (MRA) and Computed Tomography Angiography (CTA)

MRA is a noninvasive method of evaluating blood vessels, including renal arteries. Although it is regarded as attractive because of lack of radiation, this procedure requires patient cooperation such as breath holding and immobilization during scanning. In addition, MRA is time-consuming and requires sedation when performed in young children. Unenhanced (noncontrast) MRA has been found useful for visualizing renal

Table 4 Sensitivity and specificity of noninvasive imaging of renal arteries in diagnosis of renovascular hypertension. Comparison with digital subtraction angiography as reference method

	Sensitivity	Specificity
Doppler ultrasonography	73%	94–99%
Renal scintigraphy	48–86%	73–92%
Magnetic resonance arteriography	62.5–80%	63–100%
Computed tomography angiography	88%	81%

Adapted from Refs. [30, 31]

and visceral arteries in children. Additionally, the images are reported to be of the same or even better quality compared with contrast-enhanced MRA [34]. In adults, in whom the main cause of renal artery stenosis is atherosclerosis, contrast-enhanced MRA has a specificity and sensitivity of 97% and 93%, respectively [35]. In pediatric studies, nonenhanced MRA was found to have a sensitivity of 62.5–80% and specificity of 63–100% compared with DSA [30, 36].

In contrast to MRA, CTA acquisition times are very short, lasting only a fraction of a second, and the test provides good quality images. Thus, CTA can be performed even in small children without the need of general anesthesia. On the other hand, CTA requires administration of an iodine-based contrast agent and involves radiation exposure. It has higher sensitivity and specificity than MRA and better spatial resolution, which is especially important in the assessment of small intrarenal branches stenoses. Currently, MRA is recommended only when CTA is contraindicated [14]. In comparison with DSA as the reference method, CTA was found to have a sensitivity of 88% and specificity of 81% [30] (Table 4). With modern CT devices, the mean effective dose during CTA is between 3.9 and 6.3 mSv depending on the protocol, which corresponds to a radiation exposure related to 195–315 chest x-rays.

The real sensitivity and specificity of MRA and CTA is difficult to assess because the findings from these are usually the indication for referral for digital subtraction angiography (DSA). Given the low sensitivity and specificity of MRA and CTA in the diagnosis of RVH, it is important to maintain a low threshold for performing DSA even if MRA or CTA appears to be normal.

Digital Subtraction Angiography (DSA (Figs. 5 and 6)

As the sensitivity of CTA and MRA is relatively low (88% and 81%, respectively), DSA remains the gold standard in diagnosing RVH in pediatric patients with clinical and laboratory data suggestive of renovascular disease. Moreover, DSA allows for imaging of stenoses of small intrarenal,

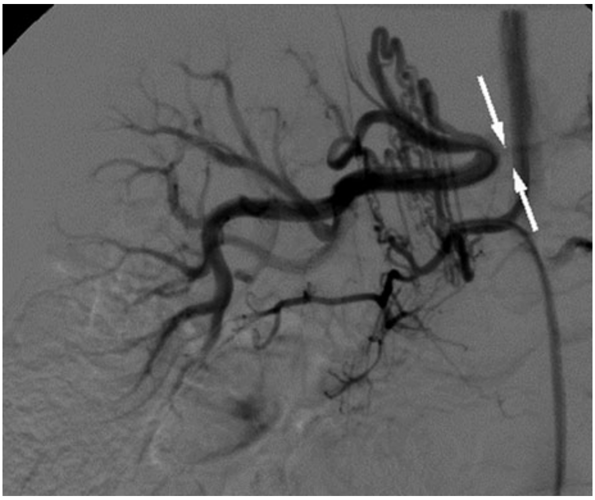

Fig. 5 Digital subtraction showing very significant right renal artery stenosis

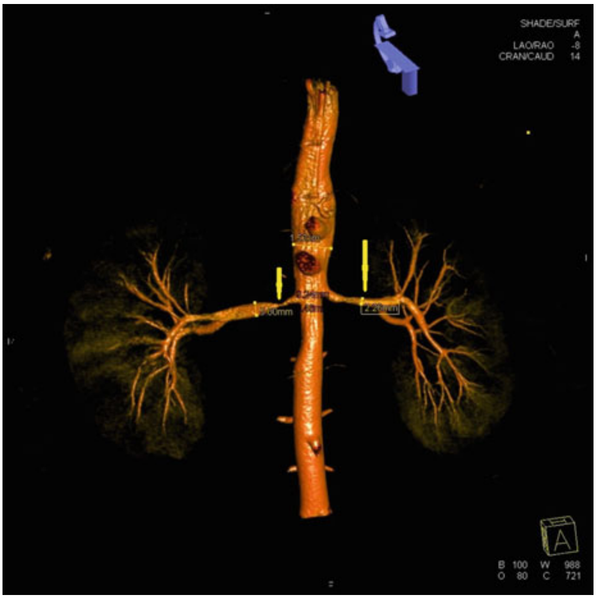

Fig. 6 Bilateral renal artery stenosis and midaortic syndrome on DSA

segmental branches of renal arteries which may be difficult to diagnose even with the use of modern, high-resolution noninvasive techniques. Because of its invasive nature, it is recommended that this procedure should be both diagnostic and therapeutic during the same session. DSA is recommended for finding the exact location and dimensions of the RAS that is suspected on noninvasive imaging such as Doppler ultrasonography and/or MRA/CTA. The other indication for DSA is severe hypertension without a clear cause identified by noninvasive imaging, especially when there is poor BP control with two or more antihypertensive medications [22].

The analysis of MRA/CTA findings makes it possible to prepare for angioplasty. The most commonly used method is the femoral approach; however, in some cases of anatomical variations of renal arteries or difficult femoral access because of stenosed or thrombosed femoral arteries, a subclavian, carotid, or even brachial approach may be used. In the situation where CTA is not performed before DSA, a cone beam CT can be performed at the start of the DSA study.

DSA requires administration of contrast usually, in a dose below 3 ml/kg body weight, but in difficult cases doses up to 6 ml/kg of body weight may be required [31].

Angiography permits making measurements of intravascular BP both proximal and distal to the stenosed segments. Intravascular ultrasonography is used in adults and makes it possible to visualize the arterial wall structure. However, there are only few pediatric reports on usefulness of this technique during angioplasty in children with stenoses of extrarenal arteries.

Renal Vein Renin Sampling

Renal vein sampling enables the assessment of renin generation by the whole kidney or its segments. This method is used when no evident stenosis is found on DSA and when distal stenoses of small branches of renal arteries are suspected. Blood samples are taken from the inferior vena cava both above and below the insertion of the renal veins, as well as from each renal vein and their intrarenal tributaries from upper, middle, and lower poles. Renin ratio 1.5: 1 between renal veins is considered as diagnostic and is supported by the finding of renin ratio below 1.3 between vena cava and contralateral renal vein. In case of intrarenal lesions, the renin concentrations in samples from different parts of the kidney are compared. Although it is believed that renin sampling may be of a greater significance in the diagnosis of ischemic part of the kidney in children than in adults, nowadays it is rarely performed.

Treatment

Treatment of RVH includes both medical and invasive therapy. Due to the complex nature of RVH and the need for a multidisciplinary approach, decisions about therapeutic management should be discussed by a team consisting of a hypertension specialist, interventional radiologist, cardiologist, and vascular surgeon. In children with RVH caused by arteritis, most commonly Takayasu arteritis, invasive treatment should be postponed until inflammatory activity is under control.

Medical Treatment

Most children with RVH present with severe hypertension and thus require antihypertensive treatment at diagnosis. However, medical therapy is only a bridge to invasive procedures such as angioplasty and/or surgery which are considered to be potentially curative. Bilateral RAS constitutes an absolute contraindication to ACEi/ARB treatment, but it is generally believed that neither ACEi nor ARB treatment should be used in children even with unilateral RVH since RAAS inhibitors may cause further ischemic injury to the already damaged kidney. It is, however, worth noting that renin-angiotensin aldosterone (RAAS) blockade with ACEi/ARBs is usually very effective at lowering BP. The mechanism of deterioration of function in the already ischemic kidney is not clear. It is assumed that RAAS blockade causes dilatation of the postglomerular efferent arterioles and, together with lowering of systemic BP, leads to an acute decrease in glomerular filtration.

There are no clear principles of pharmacological treatment of RVH. The treatment should consider presence of uni- or bilateral RAS, stenosis in other arterial beds, especially of intracerebral arteries, and electrolyte, and acid-base abnormalities caused by activation of the RAAS axis. Considering pathophysiological consequences of RAS, in the case of unilateral RAS, the contralateral kidney may react with pressure natriuresis, leading to subclinical dehydration. Thus, diuretics may aggravate sodium loss, and paradoxically, dehydration may lead to further stimulation of RAAS and BP rise. On the other hand, in the case of bilateral RAS, the activation of RAAS causes sodium retention thus making diuretics more effective.

Therefore, in our experience first-line treatment of unilateral RVH is based on a combination of a dihydropyridine calcium channel blocker, beta-adrenolytic without sympathetic activity, and alpha-adrenolytic. A mineralocorticoid receptor antagonist is used as the third or fourth line drug. Thiazide or loop diuretics are used as the last option. However, one must consider that sufficiently severe and long-lasting RVH caused by unilateral RAS may cause hypertensive nephropathy in the contralateral kidney with a patent renal artery that is persistently exposed to a high BP. Such kidney injury may lead to secondary sodium retention. In these cases, diuretics, prescribed as the second or third line drugs, are very effective. ACEi/ARBs are used in exceptional cases of unilateral RAS where other treatment options have failed. In case of bilateral RAS, diuretics, usually thiazides, combined with calcium channel blockers, beta- and alpha adrenolytics, are the first-line drugs. Mineralocorticoid receptor antagonists are also used.

In published series of children with RVH, the median number of antihypertensive drugs that were used were 3–3.4, but ranged from 1 to 8 [2, 37]. However, the efficacy of antihypertensive medical treatment of RVH was limited. Both our experience as well as the results of other groups showed that normotension was achieved only in 5–5.7% of cases, BP improvement in 21.6–43% of patients, while in 51.7–72.9% of patients, only a marginal improvement in BP was observed [1, 6]. Nevertheless, it must be noted that in most of these cases, neither ACEi nor ARBs were used.

Angioplasty

Percutaneous angioplasty is now regarded as the main form of treatment of RVH. There are several types of this procedure including balloon angioplasty, angioplasty with drug-coated balloons, cutting balloon angioplasty, and angioplasty with stents using self-expanding, bioabsorbable, and drug-eluting stents. The decision to perform angioplasty is based on the anatomical characteristics of the stenosed site obtained from CTA scans performed before or during angiography and confirmed by DSA findings. In general, ostial stenoses (i.e., stenosis at the origin of the renal artery from the aorta) are difficult to dilate and, according to some authors, are an indication for surgical treatment [38]. However, in many centers angioplasty is tried first and surgery is considered only in case of unsuccessful interventional radiology procedure.

Balloon angioplasty usually serves as the first choice procedure, but it may also be performed when reintervention is required or as a rescue therapy when complications of a procedure occur. The balloon diameter is chosen based on the diameter of renal artery proximal to the stenosed site. In recent years, angioplasty with drug-coated balloons is performed more and more frequently, usually during reintervention and with encouraging results [37]. Cutting-balloons are used in case of long segment stenosis or when there is a fibrosed area of the vessel wall such that the artery cannot be dilated with the balloon alone. Stents are generally avoided in children because of the risk of stenosis that can develop as the child grows. There is also a greater risk of in-stent stenosis caused by intimal hyperplasia and/or thrombosis. However, with increasing experience with stenting of other arterial beds and use of drug-eluting, self-expanding, and bioabsorbable stents, they are used more commonly even in children with RVH. According to recommendations, stents should be avoided in RVH in patients with FMD. However, they are used as rescue treatment in case of complications during balloon angioplasty such as dissection or severe contraction of the renal artery [14].

Angioplasty leads to normalization or improvement of BP control in 50% and, in some publications, even up to 100% of cases. However, some patients need more than one angioplasty procedure due to inadequate vessel dilatation or restenosis. In our experience, two procedures were required in 18–25% of cases and three angioplasties in 10–12% of patients.

Embolization

Embolization is considered in case of RVH caused by stenosis of segmental or subsegmental renal arteries that are not amenable to angioplasty or surgical revascularization. The embolizing substance is ethanol which causes endothelial injury and infarction of the part of the renal tissue supplied by the stenosed vessel. The loss of renal tissue is lower than with partial nephrectomy. Usually, there is no need for surgical nephrectomy/partial nephrectomy after procedure, but pediatric experience is still limited [39, 40].

Surgery

There are two types of surgical treatments: nephrectomy and revascularization. Nephrectomy is indicated in case of a poorly functioning ischemic kidney, usually with split (single kidney) GFR below 10%. However, case reports indicate that even poorly functioning kidneys may significantly improve their function after revascularization; microscopic findings have revealed that normal glomerular and tubular structure may be present in the ischemic kidney [41].

Surgical revascularization procedures are usually considered the second step after an unsuccessful endovascular intervention. An exception to this is tight ostial stenosis, wherein surgical revascularization may be considered first-line treatment. The main revascularization procedures used in children with RVH are kidney auto-transplantation (Fig. 7), renal artery reimplantation, and different kinds of bypass procedures with the use of autologous veins or synthetic grafts (Fig. 8).

Sympathetic Renal Denervation (SRD)

Sympathetic renal denervation (SRD), both surgical and endovascular, is used in treatment of resistant hypertension in adults. Although there is strong evidence from animal studies that afferent renal denervation leads to significant lowering of BP in experimental models of renovascular hypertension, SRD was not used in patients with RVH. There are, however, case reports of successful SRD in one adolescent with severe hypertension after surgical repair of aortic coarctation [42] and in a girl with Turner syndrome [43].

Outcome

The outcome of children with RVH may be recorded in several ways. The most common measure is anatomical success and improvement in BP. Many studies present results in the short or medium term. However, a significant proportion of children with RVH have a progressive condition and may, even after an initially successful procedure, represent with hypertension and need further treatment. The pathophysiology of this process is not well defined.

The greatest success of angioplasty is noted in cases with focal, uni-, or bilateral stenosis of the main renal artery with 40–85% of patients achieving normotension after angioplasty [2, 5]. In the case of RAS and intrarenal disease and/or mid-aortic syndrome, the success rate is lower and ranges from 0 to 25%; however, some improvement in BP was noted in 41.5% (25–58%) of cases [1, 2, 5, 37]. In general, single centers reports

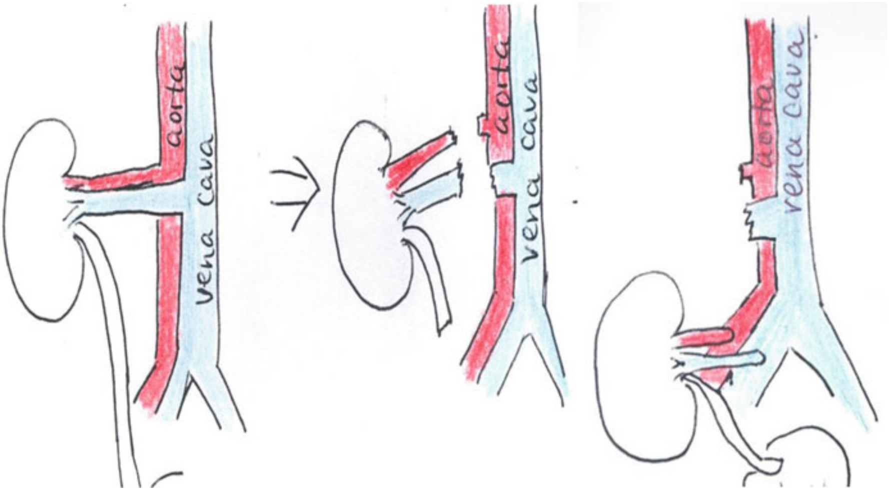

Fig. 7 The principle of autotransplantation

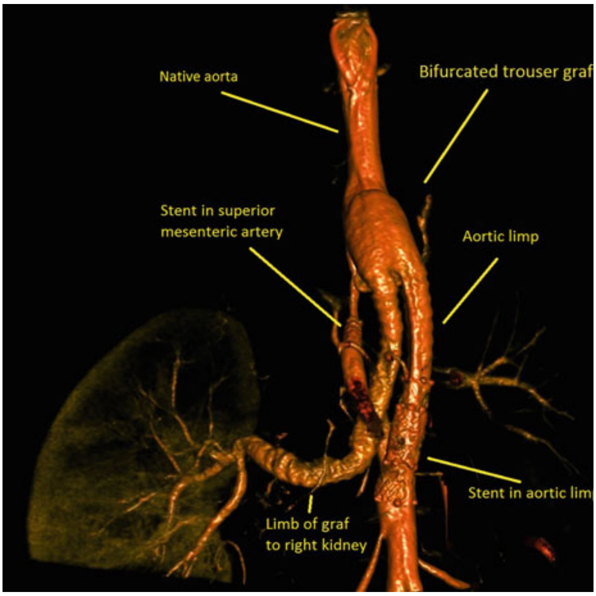

Fig. 8 Severe midaortic syndrome and bilateral renal artery stenosis treated surgically with a "trouser graft"

indicate that the median number of antihypertensive drugs prescribed decreased from 3 (1–6) to 1.3 (0–5) as a result of angioplasty. However, the procedure was ineffective in 7–23% of patients [1, 2, 31, 37].

The reported success rate of endovascular procedures appears to be similar in patients with NF1 and those presenting other etiologies. Thus, their effectiveness is thought to be related to the localization and extent of the stenotic lesion rather than to the etiology of RVH. Similarly, in patients with Takayasu arteritis, the success of angioplasty and stenting seems to be lower than in cases of other etiologies. This might be related to the extent of aortic changes rather than to the underlying disease.

The group in Michigan has the largest experience with surgery in these children. Their most recent report, using mainly classical vascular surgery techniques such as renal reimplantation to the aorta, aortorenal bypass, patch aortoplasty, and aortic bypass, shows results that are not dissimilar to those of most series on angioplasty [44]. Autotransplantation of the kidneys is a surgical method that seems to gain more and more popularity in many centers, and the short- and medium-term effects of auto-transplantation are good with up to 30–43% of patients "cured" (i.e., without a need for antihypertensive medications), and 41–50% of achieving normotension with antihypertensive drugs [45].

The outcome regarding long-term kidney function is less well reported. This should include both overall kidney function and the function of each kidney. Most series, including ours, have not reported any child who has lost both kidneys, but in a small group of patients one kidney may have to be sacrificed either through nephrectomy or because it was impossible to improve that kidney's blood flow.

A proportion of, mainly small, children have very severe heart involvement at presentation. In most cases, this seems to improve with improving BP, but very few reports have systematically looked into this issue. A surprisingly small group of children with RAS and concomitant midaortic syndrome have significant claudications. The long-term outcome of this is not fully known.

As with many childhood conditions, the transition to adult care is an important process that requires careful planning. We suggest that pediatric centers specializing in the care of children with RVH develop a long-term relation with an adult center that can take over the care of children who are likely to need long-term follow-up.

Abstract

The rapid loss of kidney function that results from renal ischemia-, sepsis-, toxic-, or toxicant-induced renal cell injury is termed acute kidney injury (AKI). The operative word “injury” initially referred primarily to renal tubule cell injury. However, it has since become clear that the expanse of cellular alterations and injury is broad, affecting other types of cells resident in the kidney that are central to the pathophysiology of AKI. This chapter focuses on the pathophysiology of AKI triggered by an ischemic insult as revealed in experimental models both in vivo and in vitro. How mechanisms of sepsis-induced AKI, a principal cause of AKI in children, overlap with and differ from ischemia-induced AKI is discussed. Included are classical concepts of acute tubular necrosis as well as a contemporary understanding of vascular, cellular, molecular, inflammatory, and metabolic alterations that are associated with renal cell injury. Mechanisms that lead to cell injury and death are addressed along with processes that can result in cellular repair and renal recovery.

Acute kidney injury · Ischemia · Sepsis · Inflammation · Cell death · Hemodynamics · Microvessels

Introduction

The sudden loss of renal function that may result from inadequate renal perfusion, arterial or venous obstruction, renal cell injury, or acute obstruction to urine flow historically was termed acute renal failure (ARF). Well over a decade ago the term acute kidney injury (AKI) was proposed to replace the term ARF [1]. Usage of “AKI” is now nearly uniform. Unfortunately, it is often used imprecisely, defeating the purpose of the change in nomenclature.

AKI was not meant to be synonymous with the old term ARF, nor the associated more narrow term “acute tubule necrosis” (ATN). The intent of the change was to standardize the definition to focus on the operative word “injury,” highlighting the spectrum of injury and mechanisms that underlie the attendant renal dysfunction. Embedded in the change in terminology was the goal to improve translation of knowledge from basic science studies to clinical studies of AKI by defining affected patients more precisely. In so doing, evaluation of potential biomarkers as predictive of severity of renal injury and outcomes could be enhanced [2]. In addition, well-defined target populations could then be chosen for translational studies of potential treatment modalities, identified in basic science studies of AKI, that had been found to limit injury or enhance recovery of injured renal cells from a specific insult.

Initially "injury," the unifying feature of AKI, was understood to be primarily renal tubule cell injury. However, it has since become clear that the expanse of cellular alterations and injury is broad, affecting other types of cells resident in the kidney that are central to the pathophysiology of AKI. The clinical manifestations of AKI range from mild but sustained elevation in serum creatinine (renal insufficiency) to anuric renal failure. In contrast, rapidly and fully reversible causes of acute renal *insufficiency*, such as from acute and reversible cardiac insufficiency or volume depletion, are specifically excluded from the spectrum of AKI [1]. Thus, the use of the term "pre-renal AKI," now rather common, is both nonsensical and antiquated, effectively reverting back to the old imprecise term ARF and accompanying terms such as "pre-renal ARF." More precise and clear, then, is to keep the term AKI separate from potentially rapidly reversible pre-renal causes of acute renal insufficiency. As intended, this can facilitate improved patient care and targeted clinical studies of AKI separate from rapidly reversible causes of renal insufficiency. The review of the pathogenesis of AKI in this chapter, then, is restricted to this precise definition.

Renal cell injury results from an ischemic, toxic (e.g., myoglobin), or toxicant (e.g., aminoglycoside) insult that causes acute tubular damage with accompanying loss of ability to reabsorb filtered solute. The resulting decrease in glomerular filtration rate (GFR), an invariable component of AKI, is then a successful adaptive response, since continued filtration of plasma across the glomerular basement membrane without reabsorption of the filtrate by injured renal tubules would result in massive losses of salt and water [3]. Thus, the decreased GFR associated with AKI prevents severe depletion of extracellular fluid.

Renal ischemia is both the most common isolated cause of AKI, and a contributor to multifactorial AKI, such as in sepsis syndrome with multiorgan dysfunction. For decades, then, studies of AKI have focused on models of ischemic renal cell injury. From these studies it is clear that AKI manifestations can range from mild, sublethal cell injury with disrupted renal cell architecture and function to fulminant necrotic cell death (i.e., ATN). Furthermore, both extremes, along with the full spectrum of intervening cell injury features, can be present simultaneously or sequentially after the insult (Fig. 1).

This chapter, then, focuses on the pathophysiology of AKI triggered by an ischemic insult as revealed in experimental models both in vivo and in vitro. How mechanisms of sepsis-induced AKI, the most common cause in children, overlap with and differ from ischemia-induced AKI is discussed. Included are classical concepts of ATN as well as a contemporary understanding of vascular, cellular, molecular, and metabolic alterations that are associated with renal cell injury. Mechanisms that lead to cell injury and death will be addressed along with processes that can result in cellular repair and renal recovery.

Phases of Acute Kidney Injury

Clinically, AKI can be divided into initiation, extension, maintenance, and recovery phases. These clinical phases directly relate to cellular events that occur during the injury and recovery process (Fig. 2). The initiation phase of AKI occurs when renal blood flow decreases to a level causing severe cellular ATP depletion that in turn leads to acute renal tubule cell injury and dysfunction [4]. Renal ischemia rapidly induces a number of structural and functional alterations in renal proximal tubule cells that are directly related spatially and temporally with disruption of the normal framework of filamentous actin (F-actin) [5–7] (described later in this chapter). The extent of these alterations depends on the severity and duration of ischemia. Although these alterations may fall short of being lethal to the cell, they disrupt the ability of renal tubules to maintain normal function. In addition, ischemic injury to vascular smooth muscle and endothelial cells during the initiation phase contribute to the structural abnormalities observed in the renal vasculature in ischemic AKI [8–10]. Activation of epithelial and possibly endothelial cells during the early initiation phase induce a variety of chemokines and cytokines that are instrumental in initiating the

Fig. 1 *Disruption and recovery of renal tubule architecture*. Ischemia disrupts normal polar distribution of membrane transport proteins and adhesion molecules, causing loss, respectively, of reabsorptive function and tubule integrity. Sublethally injured cells can recover normal structure and function. More severely injured cells die of apoptosis or necrosis, resulting in denudation and obstruction of the tubule. Restoration of tubule structure proceeds through dedifferentiation, proliferation, and redifferentiation processes likely mediated by growth factors and stem cells

inflammatory cascade ([11, 12] and see below). The cellular localization of these phenomena within the kidney continues to be elucidated.

The extension phase, which occurs during reperfusion, is ushered in by continued regional hypoxia along with triggering of an inflammatory response (Fig. 2). Both events are more pronounced in the corticomedullary junction (CMJ), or outer medullary region, of the kidney [11, 13]. It is during this phase that renal vascular endothelial cell damage appears to play a central role in the continued ischemia of renal tubules, as well as in the accompanying inflammatory response. Tubule cells continue to undergo injury and death, with both necrosis and apoptosis occurring predominantly in the outer medulla [14]. In contrast, the proximal tubule cells in the outer cortex, where blood flow has returned to near normal levels, undergo cellular repair during this phase. As cellular injury continues in the CMJ region during the extension phase, the GFR continues to fall. There is continued production and release of chemokines and cytokines that further enhance the inflammatory cascade [15]. The extension phase is thought to represent the most promising phase for successful therapeutic intervention in ischemic AKI. Leukocytes infiltrate as early as 2 h, and inflammatory cell infiltration in the outer medullary region of the kidney is significant by 24 h following ischemia [16]. So, treatments designed to interrupt the inflammatory cascade might attenuate the cellular injury and attendant loss of renal function during this phase.

During the clinical phase known as maintenance, cells undergo repair, migration, apoptosis, and proliferation so as to maintain and restore cellular and tubule integrity (Fig. 2). GFR is stable, albeit at a lower level determined by the severity of the initial event. This cellular repair and reorganization phase results in slowly improving cellular function and sets the stage for improvement in global organ function. Blood flow returns toward normal, and epithelial cells begin to restore intracellular and intercellular

Fig. 2 *Relationship of cellular to clinical phases of AKI.* Impaired renal blood flow causes the initiation phase with onset of cellular injury, particularly in the proximal tubule (*BBM* – brush border membrane). The extension phase is manifested by microvascular injury triggering inflammatory processes and causing ongoing corticomedullary junction (CMJ) hypoxia. During the maintenance phase, GFR reaches a nadir as cellular repair begins. The recovery phase is marked by progressive cell and organ structural and functional recovery, with concomitant improvement in GFR. (From Ref. [19])

homeostasis. During the recovery phase, return of cellular differentiation, epithelial polarity, and normal cellular and organ function is achieved.

Renal Hemodynamics

Renal vasoconstriction is intense in experimental and clinical AKI [17]. Because vasoconstriction was considered to be the dominant factor, it was suggested long ago that the term "vasomotor nephropathy" might be more appropriate than acute renal failure to describe this condition [18]. The hypothesis was that an insult to the renal tubular epithelium results in release of vasoactive compounds that increase cortical vascular resistance causing a decreased in renal blood flow (RBF), thus perpetuating injury to the tubule and furthering the cycle. Release of vasoconstrictive compounds may then diminish GFR by constricting afferent and efferent arterioles, thereby causing diminished urine output, or oliguria. Candidates for the vasoconstrictive components of AKI include angiotensin, metabolites of arachidonic acid, adenosine, endothelin, and nitric oxide.

Renin-Angiotensin System

The renin-angiotensin system (RAS) functions in a manner consistent with the renal vasoconstriction hypothesis. In the setting of volume depletion, reduction in renal perfusion may cause pre-renal azotemia. Prolongation of this state may result in frank parenchymal tissue damage, i.e., AKI [19]. Under these conditions, compensatory activation of the RAS system would be expected to maintain volume and perfusion pressure. In addition, because Ang II is thought to constrict preferentially efferent arterioles, its activity may be adaptive for preserving GFR in pre-renal conditions.

There is ample evidence of an increase in both local and circulating RAS components (angiotensinogen, renin, Ang II as well as other Ang-derived peptides) in patients experiencing AKI or animal models of AKI [20]. Whether the RAS participates in renal vasoconstriction leading to AKI and whether this system should be targeted clinically are questions that have failed to garner any consensus. Several studies have investigated whether the RAS contributes to the development of AKI. For example, in an animal model of ischemia/reperfusion, pretreatment with the Ang II type 1 receptor antagonist losartan prevented renal injury [21]. However, initiating hemodynamic parameters were not evaluated in the study, with the suggestion that the results may have been due to Ang II-mediated effects on inflammation. Despite such studies over many years, the role of the renin-angiotensin system as the modulator of renal injury in AKI remains uncertain.

Nevertheless, interest in this pathway remains since it appears that aldosterone, downstream from renin and angiotensin, may play a central role in ischemia-induced AKI [22]. Prior mineralocorticoid receptor (MR) blockade with spironolactone was found to prevent the typical reductions in RBF and GFR during reperfusion after ischemia, and substantially reduced accompanying renal histomorphologic damage and tubule apoptosis. The protection conferred by MR blockade correlated with changes in other pathways that have been implicated in AKI. Primarily, it appeared that MR blockade decreased oxidative stress present during reperfusion after renal ischemia.

Arachidonic Acid

Arachidonic acid (AA) is released from membrane phospholipids in the renal outer medulla in response to ischemia. AA can then be metabolized by several enzymes to produce various vasoactive compounds. One pathway is through cyclooxygenases to produce prostaglandins. Several prostaglandins are potent renal vasodilators. While inhibition of prostaglandin production is associated with decreased RBF and can affect the severity of AKI, the precise role of prostaglandins in the induction and maintenance of AKI is not established [6]. However, prostaglandin inhibitors, such as nonsteroidal anti-inflammatory drugs, increase the risk for development of AKI and may act synergistically with other insults. AA can also be metabolized to 20-hydroxyeicosatetraenoic acid (20-HETE) by cytochrome P450 ω-hydroxylase. In the kidney, 20-HETE modulates vascular tone, RBF, and sodium transport in the tubule. Further, 20-HETE has a demonstrated role in ischemic AKI [23]. Ischemia induces a dramatic increase in 20-HETE in the rat kidney and inhibition of 20-HETE synthesis worsens AKI. Administration of 20-HETE analog ameliorates ischemic AKI and prevents the typical postischemic decrease in renal medullary blood flow in rat kidneys. So, 20-HETE may mitigate AKI by preventing postischemic medullary hypoxia by increasing renal medullary blood flow [23].

Adenosine

Adenosine, which results from catabolism of adenine nucleotides, is a potent vasoconstrictor of renal vasculature, whereas it is a vasodilator of peripheral vasculature [24]. The concept that adenosine is an important vasoactive compound following an acute tubule insult is attractive, since it would link alterations in cell metabolism with hemodynamic changes. However, the evidence that adenosine is a major factor in the vasoconstrictive response in AKI is inconclusive. There is evidence that methylxanthines (an inhibitor of adenosine receptors) or the adenosine A1 receptor antagonist DPCPX improves renal function in the early phases of ischemia/reperfusion injury [25]. However, whether endogenous adenosine contributes to renal hemodynamic impairment in AKI is not clear. Adenosine levels are reduced during reperfusion injury by adenosine deaminase, despite persistent renal vasoconstriction [26]. Mice with a knockout mutation of the adenosine A1 receptor (thought to mediate tubuloglomerular feedback) had unexpectedly worse ischemic renal injury than wild-type mice, and exogenous activation of A1AR was protective [27]. The data, then, suggested that tubuloglomerular feedback through A1AR may be an adaptive response in AKI that limits delivery of solute to proximal tubules and thereby reduces the metabolic demand on susceptible, injured tubule cells.

Endothelin

Endothelin, among its various biological activities, is a potent renal vasoconstrictor [28–31]. Endothelin conveys its effects via at least two distinct receptor subtypes, the ET-A and ET-B receptors. Activation of either receptor has the potential to reduce GFR. Raised endothelin levels in plasma and in both the cortex and medulla of the kidney are found in experimental animals after induction of renal ischemia [28]. In a rat model of cold ischemic storage and transplant, preproendothelin mRNA was upregulated and immunoreactive ET-1 localized in the peritubular capillary endothelial cells following reperfusion injury [32].

The postischemic infusion of antiendothelin antibody or endothelin receptor antagonists provides protection from ischemic injury in animal models [28–30, 33, 34]. Selective ET-A antagonism inhibits afferent arteriolar constriction, while specific activation of ET-B resulted in both afferent constriction as well as efferent vasodilation [35]. In humans, there is evidence that the endothelin system may be activated in the setting of acute kidney injury. Increased endothelin levels are found in patients with AKI due to severe sepsis [36]. However, the effect of ET antagonism in humans is less clear, as it did not afford protection against contrast-induced nephropathy [37].

Nitric Oxide

Nitric oxide (NO) is a potent renal vasodilator, which is widely distributed in the kidney, and is produced from L-arginine by constitutive and inducible nitric oxide synthetases (NOS) located in endothelial cells and renal tubules [38]. The effect of either stimulation or inhibition of NOS on ischemic or toxic AKI is confusing and, at times, contradictory. The apparent contradictory effects are likely attributable to the differential distribution and specific effects of NOS isoforms on either the renal vasculature or renal tubules.

NOS3 (endothelial NOS) is produced at high levels particularly in the renal medulla [39] and its activity may represent an important mechanism to preserve medullary blood flow in response to renal vasoconstrictors such as Ang II [40]. Following renal injury, there is impaired endothelial NOS function with loss of vasodilator responses to acetylcholine and bradykinin [41]. A role for NOS3 in preserving perfusion in AKI is suggested by the greater degree of renal damage that occurs in NOS3 knockout mice in response to endotoxin [42]. Animal models have also used approaches to increase or preserve renal NO activity. For example, infusion of the precursor L-arginine, inhibition of enzyme arginase-2, infusion of NO donors, or the NOS3 cofactor tetro-hydrobiopterin can preserve renal vascular perfusion and attenuate AKI induced by ischemia [43, 44]. Clinical studies have suggested that the use of inhaled NO gas can reduce the risk of AKI in patients undergoing cardiopulmonary bypass surgery [45]. In addition, lowering of asymmetric dimethyl arginine (ADMA), thought to be an endogenous eNOS, by infusion of a novel recombinant ADMA metabolizing enzyme was recently shown to protect against ischemic AKI in rats [46].

In contrast, NOS2 (inducible NOS), either by promoting inflammation or oxidative stress, may be deleterious in AKI. Nonselective NOS inhibition was found to worsen renal function and cause profound renal vasoconstriction [47], while antisense oligonucleotides targeting NOS2 in rat kidney protected against ischemia-induced AKI [48]. Hence the dilemma: Preservation of NO in the renal vasculature via NOS3 could attenuate vasoconstriction and potentially lessen AKI; induction of NO via NOS in renal tubules is cytotoxic [47, 48]; and potential approaches to mitigate NOS should be careful to consider isoforms of NOS being targeted.

All things considered, persistent renal vasoconstriction is a well-documented event during reperfusion following renal ischemia, but once AKI has been established, the infusion of potent vasodilators such as prostaglandins or dopamine does not lead to sustained improvement in GFR [49, 50]. Confirming the findings of animal studies, several human trials of renal vasodilators such as dopamine have failed to demonstrate improvement in GFR in established AKI despite augmentation of total renal blood flow [51]. Although renal hemodynamic factors play an important role in initiating AKI, alterations in renal vascular resistance and renal perfusion on a macroscopic scale may not be dominant determinants of renal epithelial cell injury. They may, in fact, be an adaptive response to ameliorate further cellular injury during reperfusion. On the other hand, microvascular alterations are now recognized to play a major role, as discussed below.

Alterations in Microvasculature

An old and consistent observation is medullary vascular congestion following experimentally induced ischemic renal injury. Advances in recent years, including application of in vivo microscopy, has given substantial credence to the concept that injury to the vascular endothelium is central to the initiation and extension of AKI. The microvascular endothelium undergoes direct structural alterations after an ischemic insult, and is both a source of and a target for inflammatory injury [52–56]. Endothelial damage in the setting of AKI includes alteration in actin cytoskeleton structure, loss of glycocalyx and barrier function, and evidence of swelling, blebbing, and exocytosis of Weibel-Palade bodies [19, 43, 57]. In combination with chemokines liberated from nearby damaged epithelial cells, the cumulative result of these events is postulated to promote infiltration and adhesion of leukocytes within the renal microvasculature.

Minimally invasive intravital microscopy in animals has revealed sporadic cessation and even reversal of blood flow in peritubular capillaries in the renal cortex during reperfusion [58, 59]. Near-infrared laser speckle blood flow imaging shows that AKI in animal models is associated with an increase in the heterogeneity of blood flow, which is independent of total organ perfusion [60]. Such heterogeneity may underlie the focal hypoxia that contributes to the extension of renal injury during reperfusion. Administration of fully differentiated endothelial cells into postischemic rat kidneys ameliorated these early alterations in microvascular flow and the subsequent loss of GFR [59]. Similar but less impressive amelioration of AKI was achieved using surrogate cells expressing endothelial nitric oxide synthase (eNOS).

It has been suggested that alterations in microvascular perfusion patterns occur, in part, as a result of microvascular leukocyte adhesion. Ischemic AKI increases endothelial expression of a variety of adhesion molecules that promote endothelial-leukocyte interactions. These include intercellular adhesion molecule-1 (ICAM-1), P-selectin, and E-selectin [53, 61]. Ablation of the ICAM-1 gene or pretreatment with ICAM-1 antibody rendered mice resistant to ischemic AKI, raising the promise of the latter approach in humans. However, trials with anti-ICAM-1 monoclonal antibody administered postischemia did not prevent AKI manifested as delayed graft function in cadaveric transplant recipients [53]. Similarly, initial studies of animals with gene knockouts and treatment with monoclonal antibodies or pharmacologic inhibitor have suggested a role for endothelial E- and P-selectins in the microvascular injury [61–63]. Subsequent studies, though, demonstrated that platelet P-selectin, not endothelial P-selectin, is the key contributor to AKI [64]. Proposed mechanisms include initial adhesion of platelets to the endothelium with subsequent recruitment of leukocytes, or adhesion of platelets to neutrophils with consequent intraluminal cell aggregate formation and trapping in narrow peritubular capillaries [61]. Furthermore, derangements in the coagulation cascade, such as alterations in tissue-type plasminogen activator and plasminogen activator inhibitor-1 in the kidney [65], may combine with the alterations in adhesion molecules to cause the fibrin deposits characteristically found in the renal microvasculature following ischemic injury.

Taken together, while the early alterations in renal perfusion may result from physiological factors regulating vascular tone, sustained impairment of perfusion is likely the result of congestion of erythrocytes and leukocytes in the low pressure, post-glomerular vasculature, leading to the extension phase of AKI (see Fig. 2). These latter events are the likely reason for the lack of efficacy of vasodilator therapy once AKI is established [4, 19, 57, 66]. Pertinent to this issue is the recent finding that retrograde flushing of saline through the renal vein with elevated hydrostatic pressure in the postglomerular vasculature could dislodge the vascular congestion, improve perfusion and inflammation, and hasten recovery of function in rats with established AKI [66].

These observations suggest that targeting microvascular events and inflammation rather that macrovascular hemodynamic events may hold promise in treating established AKI. Despite the lack of evident benefit from the trial of anti-ICAM-1 in limiting AKI in transplant patients, new approaches in the past several years suggest that targeting the microvascular endothelium could have benefit in the setting of AKI. Examples of potential agents might include the use of pro-angiogenic agents such as erythropoietin, vascular endothelial cell growth factor or cell-based therapies using myeloid-derived angiogenic cells, or endothelial colony-forming cells [67].

Nephronal Factors

The term “nephronal factors” refers to the unique susceptibilities of specific nephron segments to injury. Best studied following ischemia are the S_3 segment of the proximal tubule (PT) and the medullary thick ascending limb (mTAL). There has been controversy over the relative importance of each of these segments in AKI [68]. What is clear, though, is that studies of cellular injury and repair in different segments of the tubule have provided important insights into the pathophysiology of tubule cell injury.

Tubule Segment Susceptibility to Injury

Medullary Thick Ascending Limb: The mTAL appears to be particularly vulnerable to hypoxia because oxygen tension in the medulla is low and the mTAL segment has high oxygen consumption [69]. This relationship was defined in isolated kidneys that were perfused with cell-free perfusate. Injury to the mTAL is prevented by increased oxygen delivery through addition of red blood cells to the perfusate. Furthermore, the degree of mTAL necrosis depended on the work load imposed on this segment. Decreasing the work load by inhibiting mTAL solute transport diminished the severity of injury; increasing the work load had the opposite effect. The relationship of these observations to the pathogenesis of AKI in man is controversial, since reducing oxygenation in experimental animals does not reproduce the lesions seen in the isolated perfused kidney model. Nevertheless, studies of the unique vulnerability of this nephron segment to hypoxia have provided insight into the relationship between oxygen supply, work load, and the cellular targets of ischemic, hypoxic, or anoxic injury [68].

Straight Segment of the Proximal Tubule: The straight segment of the proximal tubule (S_3 segment) is highly dependent on oxidative phosphorylation to supply the energy necessary for its bulk transport functions. It is particularly susceptible to ischemia and to nephrotoxins that disrupt energy supply or mitochondrial function [70, 71]. A recent study examined more precisely the long-standing question of tubule segment–specific differences in susceptibility to injury from ischemia. Using a novel model to examine single renal cell ATP levels in vivo during and following ischemia, it was found that ATP levels fell rapidly in PTs and more slowly in distal tubules (DTs). Further confirming earlier reports (detailed in the section following), ATP recovery in PTs depended on duration of ischemia. ATP recovery in DTs was rapid for all intervals of ischemia. In addition, the observed differences in ATP dynamics during ischemia and reflow correlated with differences in cell morphological changes, with PTs being more severely affected than DTs [72].

The earliest alterations in the S_3 segment, after mild or brief ischemia, are found in the brush border and consist of blebbing and internalization of the luminal membrane. With more prolonged ischemia, these changes progress to a more severe form of sublethal injury characterized by cell swelling, mitochondrial condensation, and broader disruption of cellular morphology. Simultaneous with these changes in sublethally injured cells, other cells in this segment may progress to a lethal injury such that the tubule epithelium is denuded from the basement membrane (see Fig. 1). These changes in the S_3 segment result in two important pathophysiologic events, intratubular obstruction and backleak.

Intratubular Obstruction and Backleak

Cell and brush-border debris become impacted in the hairpin turn of the loop of Henle causing obstruction and backleak of tubular fluid in some nephron segments. Intratubular obstruction following ischemic injury has been demonstrated by histomorphology and by finding elevated proximal tubular pressure [71, 73, 74]. The backleak of tubular fluid resulting from loss of tubular integrity in AKI has been demonstrated in both experimental animals and patients [71, 73–75]. In animals, microinjection of inulin or horseradish peroxidase into normal nephrons results in inulin being collected only from that kidney and staining of horseradish peroxidase only in that tubule lumen. In contrast, after microinjection into an injured nephron inulin is found to be excreted by the contralateral kidney and horseradish peroxidase is found in both intra- and peritubular loci. In patients with AKI, backleak has been demonstrated by the differential clearance of graded dextrans [75]. Since filtration is preserved and inulin, urea, and creatinine leak back into the circulation, the renal clearances of these solutes no longer represent GFR in patients with AKI. They nevertheless retain clinical utility in the global assessment of renal clearance ability.

The cellular and molecular mechanisms of tubule obstruction and backleak have been nicely defined [76, 77]. Integrins are outer membrane proteins, basolaterally located in epithelial cells, that attach the cell to the extracellular matrix. Following ischemia or ATP depletion, these adhesion molecules become detached from the extracellular matrix, allowing both dying and viable cells to leave the tubule basement membrane and float into the tubule lumen. In addition, these integrins become displaced from the basal to the luminal cell membrane domain, which allows intraluminal sloughed cells to attach to cells that remain in place, thus contributing to tubule obstruction (Fig. 1). The integrin attachment occurs via an arginine-glycine-aspartic acid (RGD) sequence [76]. The infusion of RGD peptide abolished the characteristic increase in proximal tubule pressure and substantially improved renal function following ischemia, thus confirming the central role of integrin disruption to the processes of intratubular obstruction and backleak in AKI [78, 79].

Cellular and Metabolic Alterations

Adenine Nucleotide Metabolism

Energy depletion and restoration play a pivotal role in renal cell injury [5]. In vivo, renal ischemia causes a profound fall in ATP; in vitro, metabolic inhibition of ATP production is used to induce cellular injury similar to the in vivo ischemia model. Within 5 to 10 min of inducing ischemia, nearly 90% of renal ATP has been consumed [26]. With reperfusion, renal ATP levels recover in a bimodal fashion (Fig. 3). In the first few minutes of reperfusion, there is rapid but incomplete recovery of ATP to 50–70% of normal levels, depending on the duration of ischemia [80, 81]. ATP recovery during the initial phase correlates highly with the total pool of adenine nucleotides (ATP + ADP + AMP) present in the kidney at the end of the ischemic interval. The total adenine nucleotide pool, mainly AMP, decreases as the duration of ischemia increases. So, ATP recovery during initial reperfusion is accomplished primarily by oxidative phosphorylation of the residual cellular nucleotides (AMP and ADP).

A second, slow phase of ATP recovery occurs over hours following the initial rapid phase. ATP recovery rate in the second phase also is a function of the preceding duration of ischemia; longer ischemic intervals result in slower recovery

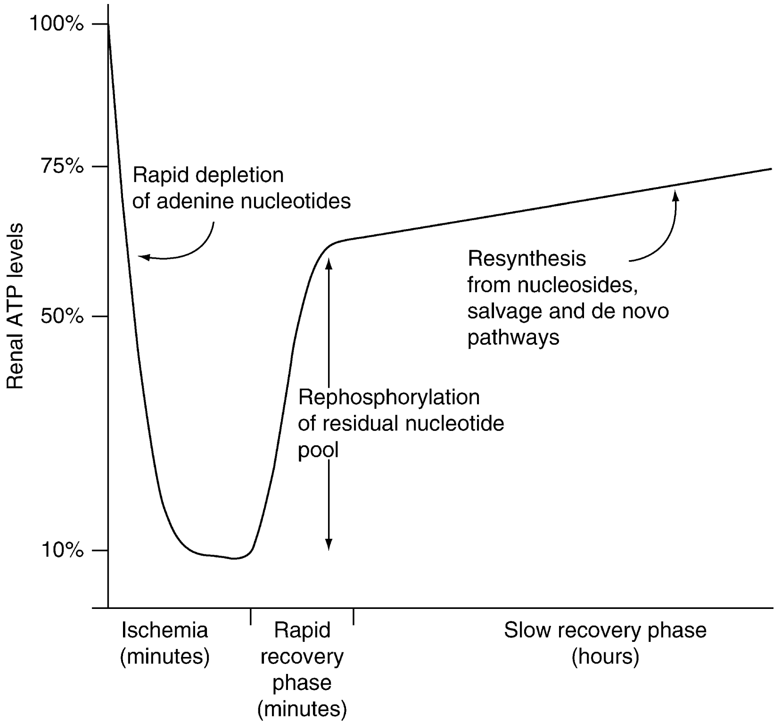

Fig. 3 *Renal ATP depletion and recovery during ischemia and reperfusion*. The initial rapid phase of ATP recovery occurs via phosphorylation of residual renal AMP and ADP. Slow phase recovery represents resynthesis and phosphorylation of adenine nucleotides

rates. The second phase requires resynthesis of ATP from purine nucleotide degradation products and salvage pathways, or from precursors provided during reperfusion (Fig. 3). A primary role for ATP depletion in ischemia-induced epithelial cell injury is supported by several findings: (1) When ATP catabolism is inhibited during renal ischemia, the structural and functional manifestations of AKI are significantly ameliorated [5, 71, 82]; (2) graded reductions in cellular ATP, either in vivo or in vitro, determine the severity of cellular disruption [83, 84]; and (3) augmentation of ATP recovery during reperfusion substantially enhances recovery of renal structure and function [5].

Restoration of mitochondrial structure and function impacts on the later phase of cellular recovery. Mitochondrial respiratory protein abnormalities persist for 6 days after the insult in two different animal models of AKI, and markers of mitochondrial biogenesis are elevated in both. So disruption of mitochondrial homeostasis persists even in the presence of mitochondrial recovery signals [85]. Administration of a pharmacological activator of mitochondrial biogenesis, after induction of AKI by ischemia, expedited recovery of mitochondrial proteins and function, along with faster recovery of markers of tubule polarization and differentiation [86].

Therefore, impaired adenine nucleotide metabolism and mitochondrial homeostasis are both a consequence and predictor of renal cell injury and recovery. Furthermore, altered ATP metabolism triggers several pathways that lead to deranged epithelial structure and function: reactive oxygen molecules, increased intracellular calcium, activation of phospholipases, and disruption of tubule cell architecture. Each of these downstream events is discussed below.

Reactive Oxygen Molecules

Reactive oxygen molecules (ROM) have been implicated in a variety of kidney diseases, including reperfusion injury after ischemia [87]. The most highly reactive oxygen molecules are free radicals such as hydroxyl radical (OH) or superoxide anion (O_2-). The high reactivity and brief existence of these molecules result in injury close to the site of free radical generation. Other oxygen species such as hydrogen peroxide (H_2O_2) and hypochlorous acid (HOCl), not being free radicals, are less reactive. However, they have longer half-lives than free radicals and may cross cell membranes to cause injury distant from their site of origin.

ROM are generated during reperfusion of kidneys [87]. Ischemia induces metabolism of the adenine nucleotides to adenosine, inosine, and hypoxanthine. Ischemia also may cause a conformational change in xanthine dehydrogenase (which uses NAD as an electron receptor) to xanthine oxidase, which uses oxygen [88]. Once perfusion and oxygen delivery are returned, xanthine oxidase can metabolize hypoxanthine to xanthine and uric acid, generating hydrogen peroxide and superoxide anion. Mitochondria, which produces reactive species though electron transport systems, when damaged by ischemia may leak the injurious oxygen metabolites. The respiratory burst and myeloperoxidase released from activated PMNs produce superoxide anion, hydrogen peroxide, and hypochlorous acid [87]. Prostaglandin metabolism may also provide reactive molecules. Iron can play a significant part by donating electrons to hydrogen peroxide to form the highly damaging hydroxyl radical. In this way, iron release may be responsible for the injury resulting in hemoglobin- or myoglobin-induced AKI [89].

Once generated, ROM damage cellular components and extracellular matrix [5]. Intracellular proteins can be oxidized, resulting in conformational changes with loss of enzymatic activity or compromised integrity of structural proteins. Membrane lipids and lipoproteins undergo peroxidation by free radicals; these propagate and result in progressive membrane damage. Hydroxyl radicals damage DNA and oxidize matrix proteins. Reactive oxygen metabolites may contribute to ischemia by deleterious interactions with nitric oxide synthetases or with NO itself. NO can combine with superoxide to form peroxynitrate, a potent oxidant.

Because of these putative actions, much attention was focused on ROM in ischemia-reperfusion injury [19, 80, 87]. Animal models show ROM involved in the pathogenesis of AKI, but whether ROM play a significant role in human AKI has long been questioned. The effects of enhancing endogenous antioxidants (superoxide dismutase, glutathione, catalase, apotransferrin, or neutrophil gelatinase-associated lipocalin, NGAL) or administering exogenous free radical scavengers (*N*-acetylcysteine, deferoxamine, or edaravone) have been examined. Animal studies have shown benefit from treatment with the antioxidants or free radical scavengers, but similar translational studies in humans, so far, have been inconclusive or have shown no benefit.

However, there was found a significant increase in oxidative stress in humans with AKI [90]. In addition, genomic studies identified an association between serum catalase and a specific catalase allele with the severity of AKI in ICU patients [91]. So, despite the large number of studies on this topic, no final conclusion can be made as to the importance of reactive oxygen species in the pathogenesis of AKI, since strong evidence exists both for and against these compounds having a dominant role.

Intracellular Calcium

Under normal circumstances, extracellular fluid calcium concentration exceeds that of intracellular free calcium (Ca_i) by a factor of 10^4. The remarkably low Ca_i is maintained by a variety of mechanisms that remove calcium from the cell or sequester it within intracellular compartments. Calcium is extruded from cells by plasma membrane Ca-ATPase and the Na/Ca-exchanger. Intracellular sequestration is mediated by Ca-ATPase in the endoplasmic reticulum and by calcium uptake into mitochondria. A fall in cellular ATP would be expected to reduce the activity not only of Ca-ATPase, but also Na/K-ATPase and thereby affect the Na/Ca-transporter. The net effect of cellular ATP depletion on extrusion of Ca from the cell and sequestration in the endoplasmic reticulum, then, would be to decrease calcium transport contributing to a rise in Ca_i. In addition, it has been suggested that release of Ca from cellular organelles contributes substantially to the rise in cytosolic Ca.

The contribution of mitochondrial damage to the observed rise in cytosolic calcium after ischemic or hypoxic injury appears to be minimal, because even damaged mitochondria are able to sequester calcium actively [80]. However, the converse effect may be a mechanism in lethal cell injury. That is, the increase in cytosolic Ca that occurs through mechanisms outlined above can lead to unrestricted uptake by mitochondria. A substantial rise in mitochondrial calcium levels, then, occurs after cell injury is lethal.

The question whether high Ca_i levels play a central role in the pathophysiology of cell injury or whether Ca_i changes are merely secondary to cell death has been controversial. Increased cell and mitochondrial Ca levels are linked to cell death, but were thought not to increase until irreversible changes had occurred [92, 93]. Later studies, however, demonstrated a reversible increase in Ca_i early in the course of cell injury in isolated proximal tubules [94]. In an in vitro model, it was found that graded levels of ATP depletion caused significant, early increases in Ca_i in renal cells, but did not cause cell death. Furthermore, the increases in Ca_i were tightly and inversely correlated to the level of ATP depletion, and preceded disruption of membrane protein-cytoskeleton interactions and induction of putative recovery mechanisms through the stress response [84]. Finally, attenuation of ischemia-induced AKI is found in mice deficient in the Na/Ca exchanger and in animals administered compounds that inhibit this exchanger, both models that would be expected to diminish the secondary rise in Ca_i mediated via the reverse mode of the Na/Ca exchanger during and after ischemia [95, 96]. Therefore, alterations in Ca_i appear not to be merely a terminal manifestation of lethally injured cells, but play an important early role in the pathogenesis of ischemia-induced AKI.

Increased Ca_i may play an early role in AKI by mediating several aspects of sublethal injury, and a later role in a subsequent transition to lethal injury after a more severe insult. An increase in Ca_i may activate calpain, contributing to degradation of the cytoskeleton; it could increase activity of other proteases and phospholipases that contribute to either sublethal cell disruption or cell death; and it could inhibit mitochondrial oxidative phosphorylation. The latter effect would lead to a vicious cycle of progressive cell energy depletion, further cell injury, and eventual cell death. However, alterations in Ca_i also could activate recovery mechanisms, such as induction of the stress response [84]. Furthermore, increased cytosolic calcium dramatically induces calcium-binding proteins such as annexin A2 and S100A6, which play an important role in cell proliferation during recovery from AKI in animal models [97]. The relative contribution that change in Ca_i makes to specific pathophysiological versus recovery mechanisms in AKI is yet to be defined.

Phospholipids and Lipases

The striking morphological changes that occur in proximal tubules after ischemia, especially brush border membrane blebbing and the release of intracellular enzymes such as lactate dehydrogenase, suggest that significant membrane alterations are part of the cellular injury in AKI. Changes in intracellular calcium flux activate endogenous phospholipase, and some phospholipase may be activated by decreased cellular ATP. Phospholipase activation causes breakdown of membrane phospholipids into free fatty acids and lysophospholipids, which can disrupt membranes and be precursors of active metabolites that promote inflammation and further activate phospholipases. Moreover, the lack of ATP during ischemia may prevent the synthesis of new phospholipids to replenish membranes. The result, then, is a generalized loss of membrane phospholipids with an accumulation of degradative products that by their detergent activities can further disrupt cell membranes, eventually leading to loss of membrane integrity and cell death (reviewed in detail in ref [98]).

As discussed earlier, another mechanism that may contribute significantly to progressive membrane deterioration is injury by oxygen free radicals. ROM generated during reperfusion peroxidate lipids, which can propagate through other membrane lipids causing widespread membrane damage. In fact, signs of lipid peroxidation provide significant evidence for free radical generation during reperfusion. It is suggested that certain phospholipase isoforms may limit, rather than enhance, membrane injury by hydrolyzing phospholipids oxidized by ROM [98]. Removal of the damaged, oxidized lipids are thereby facilitated, limiting progressive membrane damage from these toxic metabolites.

Renal ischemia causes activation of phospholipase (PLA_2) and a rapid fall in cortical phospholipid levels [99]. The detrimental effects of PLA_2 can be offset by unsaturated free fatty acids [100], suggesting that PLA_2 may be cytotoxic by degradation of phospholipids in cell membranes or through accumulation of lysophospholipids. It appears, though, that the role PLA_2 plays in renal cell injury depends on both the particular isoform of PLA_2 as well as the insult applied to cause AKI [98]. For example, cytosolic calcium-dependent PLA_2 is implicated in mediating oxidant-induced renal cell injury. On the other hand, endoplasmic reticulum Ca-independent PLA_2 appears to have a role in phospholipid repair in proximal tubules that varies according to the insult applied [101].

Just as phospholipase activity may vary according to the stimulus and domain, and either contribute to or limit the injury depending on the context, the role of lipid alterations similarly can differ in AKI. While free fatty acid and lysophospholipid accumulation may contribute to membrane damage, cholesterol accumulation appears to stabilize plasma membranes and limit renal cell injury in models of AKI. Acute tubule injury initially lowers, then increases, cholesterol content in renal tubule cells [102]. When renal cells were treated with a variety of agents to reduce cholesterol content, cell susceptibility to injury from ATP depletion was substantially increased, suggesting that cholesterol is a cytoprotectant in the context of ischemic AKI [103].

So, while the understanding of lipid alterations in AKI has become more complex, the story is similar to that of changes in Ca_i. The role of these alterations may be pathologic or adaptive, depending on the type and severity of the insult, on the location of the intracellular perturbations, and on the particular isoforms active in the affected areas.

Disruption of Tubule Cell Architecture

Renal tubule cells are highly specialized for their primary function of ion and small molecule transport, which depends on their polar structure. The change in proximal tubule cell polarity that occurs during AKI has profound effect on this function (Fig. 4) [104]. The plasma membrane of proximal tubule cells is divided into apical and basolateral domains by tight junctions shared with neighboring cells. The apical membrane, facing the tubule lumen, differs from the basolateral membrane both in lipid and membrane protein composition. The microvilli of the apical domain are rich in sodium-dependent cotransporters and Na/H-antiporters, which effect reabsorption of glucose, amino acids, phosphate, and bicarbonate along with sodium. The sodium gradient across the apical membrane, which drives the function of these transporters, is established and maintained by Na/K-ATPase located on the basolateral membrane. Plasma membrane polarity is maintained by the tight junctions that prevent lateral diffusion of membrane phospholipids and proteins into the opposite domain. In addition, the cortical cytoskeleton anchors membrane proteins, such as Na/K-ATPase, in specific domains through an intricate sequence of linked proteins. The actin-based cytoskeleton is a dynamic structure that maintains cellular polarity and mediates a number of processes necessary to sustain both structure and function of renal epithelia [105]. Interactions between cytoskeletal proteins and plasma membrane proteins are responsible for functions that include cell adhesion, endocytosis, signal transduction, and activity of ion channels.

The loss of cellular polarity is a fundamental alteration in renal epithelial injury that causes reduced transepithelial sodium reabsorption. Renal ischemia disrupts normal renal cell polarity. Proximal tubule tight junction integrity, an obstacle to diffusion of membrane components across domains in healthy tubule cells, is lost. Membrane lipids and proteins that are highly mobile

redistribute between apical and basolateral domains. Membrane proteins such as Na/K-ATPase, which normally are anchored to the actin cortical cytoskeleton, can migrate when this attachment is broken (Fig. 4). After as little as 5 min of renal ischemia there is loss and internalization of brush border membranes, and basolateral Na/K-ATPase migrates to apical membranes [104].

The actin cytoskeleton plays an important role in this process. Renal ischemia alters actin microfilaments and organized polymerization in proximal tubule cells [105, 106]. Actin disruption itself results in opening of tight junctions and loss of the polar distribution of those proteins, such as spectrin, that anchor Na/K-ATPase to the plasma membrane [81, 107–109]. Actin depolymerizing factor (ADF, also known as cofilin) participates in ischemia-induced actin cytoskeletal alterations and determines the rate and extent of these ATP depletion-induced changes in actin. ADF/cofilin is normally maintained in an inactive form by Rho GTPases. ATP depletion inactivates Rho GTPase, causing activation and relocalization of ADF/cofilin to the surface membrane [110, 111]. Concomitantly, ATP depletion dissociates the actin stabilizing proteins tropomyosin and ezrin, allowing activated ADF/cofilin to bind and cleave actin, leading to microvillar breakdown [112]. Finally, atypical protein kinase (aPKC) signaling, impaired during ATP depletion, participates in tight junction disassembly during cell injury. Furthermore, aPKC function is important for tight junction reassembly during recovery, a feature necessary for restoration of cell polarity and tubule integrity [113].

The ischemia-induced alteration of renal tubule cell architecture, then, underlies the reduction in transepithelial sodium reabsorption, which is manifested clinically as increased fractional excretion of sodium and is a hallmark of AKI. Recovery of normal sodium reabsorption occurs after normal renal cell structure and membrane polarity, in sublethally injured cells, is restored during recovery from AKI.

Cell Death

Necrosis and Apoptosis

After an insult cells can proceed down one of several pathways: recovery from sublethal injury or death by necrosis or apoptosis. Individual cells can simultaneously be moving through each of these pathways in AKI. The hierarchy of injury that results depends on the cell type, location, and severity of the insult [84, 114, 115]. Cell death by necrosis tends to follow a severe insult that leads to metabolic collapse of the cell and is more prominent in the outer medulla where the severity of the injury is exacerbated by vasoconstriction and microvascular congestion. Necrosis is massive and rapid leading to cell lysis with secondary injury to surrounding tissue. Typical features of necrosis include cytoplasmic swelling, loss of membrane integrity, and nuclear and cellular fragmentation. Cell death from apoptosis is a more regulated process that leads to cytoplasmic and nuclear shrinkage, DNA condensation and fragmentation, and eventual cell breakdown into membrane-bound apoptotic bodies. These apoptotic bodies in vivo are cleared rapidly by other cells, which has made the assessment of how much apoptosis occurs following a renal injury difficult.

While clinical acute renal failure from ischemic or toxic injury has long been called acute tubular necrosis (ATN), this term has been questioned since biopsy of patients with ARF rarely show necrotic features. However, kidney biopsies typically are late during ARF and may miss earlier signs of necrosis. Animal models of ischemic or toxic injury clearly show at least focal areas of necrosis early during reflow. Current understanding that a renal insult can lead to simultaneous sublethal and lethal injury (necrosis or apoptosis) in cells in different areas of the kidney has led to the change in terminology from ARF or ATN to acute kidney injury (AKI, see introduction) [1].

Measuring apoptotic cell death in vivo has been problematic, leading to controversy over whether this is an important pathway in AKI. Definitive morphologic criteria have established and confirmed apoptosis as a pathway to cell death in renal epithelia both in vivo and in vitro [116, 117]. Biochemical assays can be helpful to quantify apoptosis, but are not uniformly reliable in vivo or in vitro, unless traditional cell morphology criteria are also applied. For example, neither endonuclease activation nor DNA laddering consistently discriminate between necrosis and apoptosis in injured renal epithelia [118, 119]. However, the specificity of TUNEL staining for apoptosis in several forms of in vivo renal cell injury was determined using accepted morphological criteria and was found to be 99% specific in vivo ischemic renal injury [120]. These studies indicate that apoptosis is an important mechanism of cell death in AKI leading to exploration of apoptotic pathways that might be active after a renal injury.

The process of apoptosis has been separated into three sequential phases: initiation, commitment, and execution phases. The initiation phase can be activated by extrinsic factors or intrinsic cell stress [19, 121]. Membrane receptors and the Fas pathway can contribute to the extrinsic initiation phase of apoptosis in ischemia, and interference with this pathway can ameliorate in vivo AKI [122–125]. Intracellular derangements in cell architecture, metabolism, and function during ischemia are likely a major trigger to the intrinsic pathway for initiation of apoptosis following ischemia.

Central to the commitment phase of apoptosis are several changes in mitochondria. Loss of mitochondrial transmembrane potential is pivotal to the cascade; interventions preventing mitochondrial permeability transition avert apoptotic nuclear and cell membrane alterations [126–129]. Bax translocation from its cytoplasmic pool to mitochondria contributes to opening of mitochondrial pores with subsequent release of cytochrome C [130–132].

Bax-mediated apoptosis has been demonstrated in cultured proximal tubule cells following ATP depletion [132]. An imbalance between the pro-apoptotic (Bax, Bid) and antiapoptotic (Bcl-2, Bcl-xL) members of the Bcl-2 protein family, as well as the proapoptotic protein p53, are implicated in the commitment phase of apoptosis in both animal [133–135] and human [136–138] conditions of ischemia-induced AKI. Though cytochrome C release from mitochondria is not specific for apoptosis, it follows the mitochondrial permeability transition that is modulated by the Bcl-2 protein family and indicates commitment to cell death. Its release is an essential factor in causing downstream activation of the effector proteins for apoptosis [115, 126, 132].

Caspase 3 is the effector protein that lies at a critical juncture in apoptosis pathways. Activation of caspase 3 begins the execution phase of apoptosis [139–141]. A series of additional caspases are activated in the execution phase that cleave multiple cellular proteins, including cytoskeletal-associated proteins and endonuclease inhibitors, resulting in the characteristic morphology of apoptosis – cell shrinkage, membrane blebbing, nuclear condensation, and fragmentation [115].

Autophagy

Autophagy is a cell stress response involving bulk degradation of damaged organelles, protein aggregates, and macromolecules in cytoplasm. This cellular mechanism is suggested to be an adaptive response that protects against AKI by limiting cell death. Indeed, studies indicate that blocking autophagy pharmacologically or genetically accelerates apoptosis [142]. As such, autophagy may be a pathway to be manipulated in preventing AKI.

Inflammatory Response

Although studies many years ago suggested that the immune system had no role at all in ischemia-induced AKI, a growing body of evidence in the past several years indicates that the inflammatory response plays a major role in AKI [53, 143, 144]. The inflammatory cascade is initiated at the vascular endothelium. Renal injury leads to increase in the expression of leukocyte adhesion molecules ICAM-1 and P- and E-selectin on endothelial cells, and interference in these pathways results in less inflammation and injury after renal ischemia [145–148]. Inflammatory cascades initiated by endothelial dysfunction can be augmented by potent mediators generated by the ischemic proximal tubule. Both pro-inflammatory cytokines (TNF-α, IL-6, IL-1β, and TGF- β) and chemotactic cytokines (MCP-1, IL-8, and RANTES) are generated following renal ischemia and can enhance inflammation [144, 149–153]. Strategies to modulate the inflammatory response by altering cytokine action have been tried in AKI. Modulation of IL-6 and IL-10 have demonstrated initial results to reduce overall inflammatory injury. Signaling of Toll-like receptors (TLR) on immune cells from any stimuli causes an inflammatory state, which when uncontrolled can lead to tissue damage [154–157]. The common mediators of signaling from the TLR family include TLR-2 and TLR-4. Inhibition of TLR-2 by gene knockout or antisense treatment prevents ischemia-induced renal dysfunction and suppresses some cytokines in cultured proximal tubule cells [157, 158]. Conflicting findings of studies on TLR pathways in AKI indicate not only that the effect may vary according to the particular renal insult, but that TLR pathways need to be explored in more detail to define clearly their role in AKI.

Cellular and chemical signal disruption may be prominent in inflammation associated with AKI. Cellular attraction and chemoattraction of cytokines and chemokines by injured kidneys have been documented following ischemia [143, 146, 153, 159–164]. The significance of neutrophil infiltration is not clear because neutrophil depletion or blockade of function provides only partial protection and only in some animal models, and neutrophil infiltration appears not to be a prominent feature of ischemic renal injury in humans. Selective macrophage depletion and manipulation of macrophage infiltration into the kidney decreases the severity of AKI [165–167]. Macrophages are dependent on coordinated action of T cells and neutrophils. Although it is the most abundant immune cell in the kidney, the role of the dendritic cell in AKI is not known.

T and B cell determinants of inflammation are also contributory in AKI. The role of T cells has been intensely studied; they have been found in the kidney in both human and rodent ischemic AKI [144, 153, 168]. Reversal of protection in the latter model occurs with adoptive transfer of wild-type T cells into the knockout mice. T regulatory cells were determined to have a fundamental role in balancing the inflammatory response within the kidney in AKI [169–171]. Resistance to developing AKI following preconditioning is attributed to T regulatory cells. Along with numerous agents that promote proliferation, function, and trafficking of endogenous T regulatory cells, studies using adoptive transfer of T regulatory cells indicate their protective role in AKI [172]. Compared with wild-type animals, B-cell-deficient mice kidneys, with comparable T cell and neutrophil infiltration following ischemic renal injury, are partially protected both structurally and functionally [146, 148, 164, 172–174].

Ischemia-reperfusion injury in most organs activates the classical pathway of the complement cascade. However, the alternative pathway, along with the mannose-binding lectin pathway of complement activation, appears to predominate in ischemic AKI in animals and humans. Studies focused on C5a, a powerful chemoattractant for inflammatory cells, suggest that it contributes to renal injury and impairs recovery. Another complement protein, factor B, may also have an integral role in augmenting the inflammatory response in ischemic AKI [175–178].

The clear involvement of the immune system in ischemic AKI suggests a mechanism underlying the consistent observation that development of acute kidney injury substantially increases overall morbidity and mortality in patients suffering from a variety of diseases, including isolated cardiac disease, sepsis, and multiorgan dysfunction. In that context, it has been intriguing to see animal studies documenting distant organ effects and dysfunction in the heart, lungs, and brain after isolated ischemic AKI [149, 153, 160, 179–181]. It has been suggested that these distant effects of renal ischemia may be mediated by inflammatory signals generated in the injured kidney.

Sepsis-Induced AKI

Sepsis and acute kidney injury synergistically increase morbidity and mortality in hospitalized patients. Sepsis is the leading condition associated with AKI [182]; the BEST kidney study reported an AKI incidence of 5.7% in 29,000 patients with sepsis being the highest associated etiology (47.5%) [183]. Analysis of 276,731 admissions to 170 adult critical care units in the UK identified concurrent sepsis and AKI in 8246 ICU admissions in the first 24 h [184]. Sepsis-associated AKI (S-AKI) is common in children, particularly in the developed nations. Though separate entities, sepsis and AKI carry considerable pathophysiologic overlap and significantly worsen patient outcomes when concurrent. Sepsis is the condition most associated with AKI in critically ill patients, so significant effort has been expended to understand the pathophysiologic drivers of each separately and together. Despite abundant epidemiologic data describing incidence and associated outcomes, understanding of the complicated pathophysiology driving S-AKI is only superficial, appreciation of the disease phenotype is lacking, and current diagnostics are outdated. Ultimately, these shortcomings contribute to a deep knowledge deficit, resulting in a paucity of focused and effective therapeutic options.

The pathophysiology of S-AKI is multidimensional and occurs on the microscopic and macroscopic level [185–189]. A combination of subcellular inflammatory dysregulation, cellular end events ranging from apoptosis to necrosis to quiescence, endocrine and paracrine oxygen delivery (DO_2) dysregulation and dysoxia at the end-organ level, and aberrancy in blood flow and perfusion are all believed to be mediators of S-AKI. Both murine and ovine models have been used to delineate the drivers of injury in S-AKI including: direct endotoxin administration using lipopolysaccharide (LPS) through intraperitoneal or intravenous injection, direct live bacterial instillation (either gram negative or gram positive), cecal ligation and puncture (CLP) with fecal implantation, and surgical bacterial implantation [185, 186, 190]. In addition to the pro-inflammatory and chemoattractant signals discussed in the previous section, the importance of the pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) have been identified in relation to pathogen recognition receptors such as TLRs [191–194]. DAMPs and PAMPs directly and indirectly induce renal tubular damage and contribute to loss of function. Oxidative stress is associated with renal tubular damage. In LPS models, endocytosis by S1 tubular epithelial cells triggers an oxidative burst in the S2 tubular segment cells, potentially secondary to suppression of heme-oxygenase 1 and Sirt1, both being protective against oxidative damage [195–198]. Oxidative stress then affects the balance of cell survival, arrest, necrosis, or apoptosis. Proapoptosis gene regulation is notably increased in models of S-AKI, particularly by altering GSK3β function, which is known to balance TNF-α and other regulators of apoptosis. Endothelial activation is not only triggered by the interleukin inflammatory cascade but also modulated by TNF-α mediated caspase-8, identified as a mediator of AKI in sepsis but not in ischemia. Other apoptotic mediators such as p53, p21, bax, and cyclin-dependent kinase 2 are also implicated, identified by therapeutic interventions such as zVad pancaspase inhibitor, PI3k/Akt antiapoptotic pathway activators, and JNK inhibitors in animal models [165, 174, 181, 199–201].

A significant point of interest is the role of the dysregulated inflammatory system in S-AKI and whether this is distinct from ischemic AKI. Comparison of gene dysregulation in the separate models of AKI help elucidate the differences. In CLP models of AKI, compared with ischemic models of AKI, NF-kb/MYD-88 signaling of the pro-inflammatory transcriptome appears to contribute significantly to the inflammatory process in the kidney, outside of independent renal production of these gene transcripts. Sepsis itself appears to modulate TLR-4 responses, as seen in TLR-4 knockout mice subjected to CLP compared with the ischemic AKI model. This raises a fundamental question. Is kidney dysfunction during sepsis an effect of the host response to infection and inflammation (i.e., the kidney is an "innocent bystander") or is the kidney independently responsible for propagating injury and inflammation? This differential paracrine versus autocrine response is poorly understood at this time, but has clear clinical implications for protection or recovery of renal function in sepsis [149, 159, 160, 202].

Histopathology demonstrates wide variability in the phenotype of septic AKI in humans. Although both murine and ovine models indicate that apoptosis is more common than necrosis, the available evidence suggests that neither are common in human S-AKI. Less than 20% of available biopsy results show any morphological aberration in tubular or mesangial cells or distortion of architecture. The animal models of CLP, small or large animal, show that necrosis is not a typical finding in sepsis-associated AKI [186, 203–206].

Differences in renal perfusion in sepsis compared with ischemia may explain the discrepant findings of histopathology, inflammation, and cellular survival in the two forms of AKI [204, 207]. In contrast to ischemic AKI, increased renal blood flow and glomerular perfusion are the norm in ovine models of LPS-induced AKI. Renal blood flow during S-AKI has direct correlation with cardiac output. Sepsis has asymmetric effects on the afferent and efferent renal arterioles, with relatively reduced efferent arteriole resistance in that setting. The net effect is to reduce transglomerular pressure, thereby reducing GFR.

The issue in sepsis, then, appears not to be about oxygen delivery per se, but poor oxygen utilization, or dysoxia. Sepsis-induced disruption of bioenergetics is manifested by reduced glycolytic capacity, reduced glycolytic reserve, and reduced ATP reserve production in CLP models. The role of mitochondria in ischemic AKI has been extensively explored, and the gene targets of the PPAR and PGC-1a are implicated in the bioenergetics failure resulting from pedicle clamping or hypoperfusion models [208–211]. Mitochondria are also common targets of inflammatory injury induced by sepsis, leading to dysfunction and increased production of injurious reactive oxygen species.

Endothelial injury in septic models affects vascular permeability throughout the kidney, including in the glomerulus and peritubular microvasculature, facilitating inflammation with fluid extravasation and propagating organ injury. A related phenomenon is hyperviscosity and sludging in the microvasculature. Microthrombi formation can be seen within 4 h after CLP, thought to be secondary to production of reactive oxygen and nitrogen species.

In sum, then, several concurrent processes contribute to an environment within the kidney to cause sepsis-induced AKI. Among these include the endothelium in the microvasculature and renal tubule epithelia being primed for dysoxia and poor oxygen uptake during sepsis and ischemia. Given the evidence, the scope of injury in S-AKI suggests that the direct dysregulation found in ischemic models of AKI, including immune trafficking by chemoattractants and macrophage-monocyte infiltration, is as detrimental to function as the indirect effects of sepsis-mediated injury.

The renal system can participate in protection from sepsis-triggered AKI mediators. Several animal models have shown induction of mitophagy, autophagosomal capture of dysfunctional mitochondria, during the production of oxidative species in sepsis [212–215]. In addition, cell cycle arrest early in sepsis may be an important defense mechanism against injury to cells in the nephron, thereby helping prevent energetic failure in the affected cells and limiting propagation of injury. To this end, the cell cycle arrest marker TIMP2/IGFBP7 (tissue inhibitor of matrix metalloproteinase 2/insulin-like growth factor binding protein 7) is a validated marker of AKI in septic critically ill patients.

Identification of potential therapeutic targets in S-AKI depends on understanding the individual processes propagating injury (Fig. 5). A unified theory of sepsis and AKI could incorporate the individual cellular and subcellular drivers of injury. These range from the inflammatory danger signal (DAMPs and PAMPs) to the oxidative stress and perturbed oxygen delivery, and to the aberrant renal blood flow and dysregulation of vascular tone (mediated by ICAM and selectins described earlier). However, differences in the insults causing AKI indicate that the balance of oxidative stress and locally acting cytokine

mediators appears to induce a state of pro- or antiapoptotic forces in S-AKI, debunking the previously held dogma that equated septic AKI with acute tubular necrosis.

Currently, the animal and in vitro models of sepsis and AKI carry both strengths and limitations. The nonsurgical models remain easier and less expensive but are often not physiologic and vary significantly in reproducibility of findings from in vivo models. In addition, the surgical models of S-AKI suffer from the lack of a precise equivalent in humans. Specifically, CLP is not a mimic for nonabdominal sepsis. Nevertheless, these models have substantially advanced our understanding of the pathophysiology of sepsis as a major cause of AKI, and how mechanisms triggered by sepsis coincide with or differ from ischemia-induced AKI. Moving forward, continuing to define precisely biological markers of cellular injury may facilitate their clinical implementation in various forms of AKI. In so doing, well-defined biomarkers could improve prognostication, and further help untangle the complex and unique biology of sepsis-associated AKI from both sepsis alone and ischemia-induced AKI.

Genetic Susceptibility

In the clinical realm, it has long been observed that the incidence or severity of AKI varies widely between patients who have apparently been subjected to the same renal insult. While unrecognized environmental factors certainly play a role, this observation has led clinicians to suspect that individual patients may have an inherent genetic susceptibility or resistance to developing AKI. This has led investigators to explore whether differences in genetic background affect the risk of developing AKI.

Specific human genetic polymorphisms have been linked to either resistance or susceptibility to develop AKI. These human studies have implicated genetic polymorphisms of pro- and anti-inflammatory cytokines and heme oxygenase-1 (HO-1) as potential determinants of susceptibility to ischemic renal injury [216]. Genetic polymorphisms of the stress protein Hsp72 were associated with neonatal susceptibility to develop AKI. The Hsp72 (1267) GG allele has low inducibility of the Hsp72 protein. Neonates carrying the Hsp72 (1267) GG genetic variation had increased risk of AKI [217, 218]. Furthermore, several maternal and fetal cytokine genetic polymorphisms were linked to the incidence and severity of sepsis, necrotizing enterocolitis, and eventual AKI [218].

The proliferation of such studies led to a systematic review to determine whether any polymorphism could be conclusively associated with AKI. Of 35 individual polymorphisms whose association with AKI had been reported and examined in the review, only 1 polymorphism, *APO E e2/e3/e4* (a regulator of inflammation), had more than one study showing a significant impact on AKI incidence [219]. However, that association was not confirmed in a larger study. The authors concluded that since current association studies do not provide definitive evidence linking specific genetic variations to AKI, a different approach is required. They conclude the need to restrict such studies to a narrow consensus definition of AKI (as discussed in the introduction to this chapter), and a shift from a priori hypothesis-driven to genome-wide association studies [219].

Studies of different rat strains give credence to this approach, along with the concept that genetic background can substantially influence vulnerability to AKI. The inbred Brown-Norway (BN) rat strain is profoundly resistant to developing AKI following ischemia when compared with other inbred and outbred rat strains [220]. The strain specific protection appears to be on a cellular level since immediate cellular manifestations of ischemic AKI are limited, and the protection is sustained. The specific mechanism providing this protection is yet to be determined, but that it is related to differential gene expression is indicated by the finding of increased constitutive expression of putative cytoprotectants in the protected strain.

To define the genetic basis for resistance to AKI further, consomic rats were studied, in which individual chromosomes from the AKI-resistant BN rat were placed into the genetic background of an AKI-sensitive rat strain. Nine chromosomes on consomic strains were found to contain alleles that afford protection against developing AKI [221]. So, full protection against ischemic injury in the BN rat likely is from multiple beneficial alleles working in concert. In silico analysis identified at least 36 candidate genes on the chromosomes found to contain protective alleles, with several candidate genes previously linked to the pathophysiology of AKI [221]. So natural variants of these alleles, or yet to be identified alleles on the chromosomes identified to harbor protective genes, provide protection against AKI in the rat. Since both the rat and human genomes have been fully sequenced, the results from this study might guide translational studies in humans to identify modulators of AKI in susceptible patients. This might then allow identification of individuals genetically predisposed to develop AKI in a specific clinical setting.

Biomarkers

Advances in functional genomics and cDNA microarray-based technologies have revealed the landscape of the numerous pathways activated by acute kidney injury [222–226]. Novel genes with altered expression and new signal transduction pathways have been discovered that may serve as biomarkers of AKI. The ectodomain of kidney injury molecule-1 (KIM-1) protein, upregulated following ischemia on the apical membranes of proximal tubule cells, is cleaved and released into tubule lumen. This sliced part of KIM-1 is detected early in urine even with mild proximal tubule injury from a variety of causes. Increase in urinary KIM-1 has been shown to be prognostic in several human studies, making it a promising noninvasive urinary biomarker of AKI [227].

Neutrophil gelatinase-associated lipocalin (NGAL) is rapidly expressed in kidney cells in response to several forms of stress and are detected in low levels in serum of healthy individuals. NGAL filtered in the glomerulus is reabsorbed in the proximal tubule, resulting in only low levels in urine. Decreased proximal tubule absorption of filtered NGAL in AKI, in combination with increased production by distal tubular epithelial cells, leads to increased NGAL levels in urine. Tumors, sepsis, and leukocyturia, without any renal injury, can also result in increased NGAL levels, making them important confounders when interpreting NGAL data. Though reference values have been established in healthy adults (higher levels in women and increasing with age), progress with this biomarker will require specific informative cutoff values for the different clinical situations [228, 229].

Additional urinary biomarkers identified as detecting early kidney injury include cystatin C, N-acetyl β-D-glucoseaminidase (NAG), and interleukin 18. Any individual biomarker, if accepted as a biomarker of renal injury, can help overcome the shortcomings of serum creatinine as a measure of AKI, which include the inability to differentiate early between established kidney injury and reversible hemodynamic changes resulting in physiologically reduced GFR. Since each biomarker has unique strengths and weaknesses, using a marker panel might be more reliable in determining the type and severity of kidney injury, and allow for more precise prognosis models [230, 231].

Repair Mechanisms

Just as multiple pathways to cell injury are activated in AKI, the repair processes would be expected to be multifaceted. The mechanisms to renal recovery, then, might include: a) endogenous repair of sublethally injured cells, b) proliferation of surviving renal tubular cells, or c) replacement of dead cells by stem cells. The rapid initiation of repair in injured tubules supports the theory of endogenous repair of sublethally injured cells [232–234]. A deep understanding of the recovery process could identify interventions that augment cellular repair to restore kidney function more quickly and fully.

Heat Shock Proteins

Heat shock proteins (Hsps), also called stress proteins, are elaborated in cells in response to a variety of injurious stimuli. Hsps function as protein chaperones and are essential to basic cell function and survival by providing routine assistance in intracellular protein handling [235]. The two stress protein families most studied in AKI are the Hsp70 and the small Hsp 25/27 class. Heat shock transcription factor-1 (HSF-1) activation, the initiator of the stress response, is rapid after onset of renal ischemia. Significant Hsp induction in the kidney soon follows [83, 236, 237].

Renal tubule cells that suffer loss of structural integrity in AKI regain their normal architecture and polarity through remodeling [104]. Recycling of damaged proteins by the chaperone capacity of Hsps appear to be central to the repair process. Hsp72 binds specifically to disrupted Na/K-ATPase, and Hsp25/27 binds specifically to disorganized actin filaments in renal epithelial cells injured by ischemia or ATP depletion [238–240]. Furthermore, both Hsp72 and Hsp25/27 have been shown to be protective against injury from in vitro ischemia in proximal tubule cells [239–241]. Hsp72 and 25/27 appear to work synergistically to preserve renal cell structure [242].

Supporting the in vitro studies, proximal tubule cells isolated from transgenic mice that overexpress human Hsp27 are tolerant to hydrogen peroxide injury. However, these same mice manifest more severe ischemic AKI in vivo [243]. The worse renal outcome in vivo was attributed to increased pro-inflammatory gene expression with increased neutrophil and lymphocyte infiltration into the kidney early after ischemia. In contrast to systemic Hsp27 overexpression, selective renal overexpression of Hsp27 protected against ischemic renal injury in vivo [244]. With renal-specific Hsp27 overexpression, protection against AKI was attributed to decreased neutrophil infiltration of kidneys and reduced pro-inflammatory gene expression.

A more actively primed stress response may contribute to the phenomenon, long recognized by clinicians, that the immature kidney appears to be resistant to insults that produce profound AKI in older patients. As in patients, immature rat kidneys are more resistant to ischemic injury than their mature counterparts. The neonatal rat kidney has increased constitutive activity of HSF-1 compared with mature animals, with accompanying increased expression of Hsp72 [245, 246]. Blocking HSF-1 function reduces Hsp72 expression and the tolerance of isolated immature renal tubules to anoxia [245–247]. Stress proteins, then, appear to be central to the resistance of immature kidneys to ischemic or anoxic injury.

It was thought, therefore, that the cellular stress response regulated by HSF-1 would also be central to resistance to in vivo AKI in mature animals. It was a surprise, then, when it was found that HSF-1 knockout mice, with absent Hsp induction following renal ischemia, are resistant to developing AKI after an ischemic insult [248]. HSF-1 knockout mice were found to have an increased baseline level of immunomodulatory Foxp3+ regulatory T cells resident in the kidney. This appears to prevent the development of usual features of AKI seen in kidneys shortly following an ischemic insult, specifically the pro-inflammatory environment and the typical medullary vascular congestion.

Thus, Hsps clearly provide protection at the cellular level in renal tubules, but the systemic effect of inducible Hsps may instead be harmful in the setting of an in vivo ischemic insult. Detrimental effects of inducible Hsps, outside of the renal tubule and in the microvasculature, may conflict with their beneficial effects within renal tubule cells subjected to ischemia by facilitating pro-inflammatory mechanisms of renal injury. The most recent studies, then, uniquely connect the rapidly inducible cellular stress response, regulated by HSF-1, to pathways of inflammation in ischemia-induced AKI.

Regeneration: Growth Factors

It has long been suspected that growth factors, produced locally or exogenous to the kidney, contribute to proliferation and redifferentiation of the tubule epithelial cell following AKI (Fig. 1). Many studies have supported this concept. These include epidermal growth factor (EGF), insulin-like growth factor-1 (IGF-1), hepatocyte growth factor (HGF), parathyroid hormone–related peptide (PTHrP), basic fibroblast growth factor, osteopontin, neural cell adhesion molecule, transforming growth factor beta 1 (TGF-β), Klotho, and fibroblast growth factor 23 [233, 249–252]. The plethora of growth factors that appear to have a role in renal recovery in AKI raises questions about each factor's specific site of action, potential interaction or overlap of activity between separate growth factors, the specific cellular processes each factor impacts, and the relative importance of each factor in the recovery from AKI. It is not a surprise that growth factors are found to be active in several pathways pertinent to AKI.

Growth factor function may be intimately linked to processes of apoptosis. In the rat model of AKI, expression of pro- and antiapoptotic members of the Bcl-2 gene family (Bcl-2, Bcl-X (L), Bax) are related to tubule expression of EGF, IGF-1, and TGF-β, all growth factors thought to be reparative in AKI [251]. The study suggested that the distal tubule is resistant to ischemic injury through antiapoptotic effects of Bcl-2 genes, and its survival allows expression of growth factors critical not only to the survival and regeneration of its own cell population (autocrine action), but also to the adjacent ischemia-sensitive proximal tubule cells (paracrine action).

AKI in rats increases expression of transcription factors Ets-1 and Wnt-4 that are in pathways involved in cell cycle progression [253]. Nephrogenic proteins basic fibroblast growth factor (bFGF), vimentin, neural cell adhesion molecules, paired homeobox-2, bone morphogene protein-7, Noggin, Lim-1, Engrailed, Smad, phospho-Smad, hypoxia-inducible factor-1 alpha (HIF-1 alpha), vascular endothelial growth factor (VEGF), and Tie-2 are all induced by renal ischemia in a pattern similar to that seen in normal renal development, and administration of bFGF-accelerated induction of many of those nephrogenic proteins during recovery [254, 255]. HIF-1 alpha is rapidly activated by renal ischemia, and growth factors VEGF and erythropoietin, both regulated by this transcription factor, appear to have important effects on renal epithelial cells and endothelial cells in the renal microvasculature. Erythropoietin administration prior to renal ischemia protects the kidney against the injury through mechanisms that limit apoptosis [256].

The relative importance of the many growth factors identified to be active in AKI has rarely been addressed. One study, however, directly compared the effect of two of these growth factors in AKI using a transgenic mouse model with targeted overexpression in the proximal tubule of HGF in one strain, and PTHrP in another strain. The strain with increased HGF in the proximal tubule had a fourfold increase in tubule cell proliferation and a threefold decrease in apoptotic tubule cell death, along with rapid recovery from ischemic injury, compared with either the mice with targeted proximal tubule overexpression of PTHrP or background strain control mice [257]. This study confirmed the importance of HGF during the recovery process, but raises questions about the role of rapid PTHrP induction in the proximal tubule after renal ischemia. By extension, it also raises questions about all of the growth factors identified as being induced by renal ischemia whose functional effects are yet to be defined. Some may be beneficial. Some, such as TGF-β, may have detrimental effects in the long term. A delicate balance of these factors may determine whether tissue remodeling following renal injury results in restitution of normal architecture or proceeds to a dead end of irreversible fibrosis.

Regeneration: Stem Cells

With the advent of stem cell research, the possibility that some form of stem cell might be integral to kidney repair after AKI rapidly came to the fore. Embryonic and nonembryonic/adult stem cells, the latter from several sources, can differentiate into more than one type of specialized cell. Mesenchymal stem cells residing in the bone marrow can differentiate into a variety of mesenchymal tissues in vitro and in vivo. Tissue-specific progenitor cells may reside in any organ and can differentiate into a range of cells as the need arises. Each of these potential sources of stem cells have been studied to determine the contribution to renal repair following AKI.

Initial studies supported the concept of bone marrow–derived stem cells (BMDSC) homing to ischemia-injured kidneys, and differentiation of noninflammatory bone marrow derived cells into renal tubule cells [258–260]. However, subsequent studies showed that BMDSC contribute minimally to repopulation of tubular epithelia [261–265]. It now appears clear that repopulation of denuded tubules after AKI comes from proliferation of surviving intrinsic kidney cells, rather than from exogenous or endogenous stem cells [263].

Nevertheless, BMDSC have a role in the repair process. The severity of renal injury in bone marrow–ablated mice was worse than without ablation and was reversible with infusion of lineage-negative bone marrow cells [259]. Although mesenchymal stem cells (MSCs) may not engraft into renal tubules, they have functional effects in AKI, such as blunting the rise in serum creatinine and altering pro-inflammatory cytokine and growth factor expression [261, 266]. These findings suggest that protection by MSC may be mediated by paracrine or endocrine actions [266, 267]. Furthermore, mobilizing endogenous BMDSCs may be a therapeutic option in AKI using stem cell factor or colony-stimulating factors (macrophage-CSF or granulocyte-CSF) [268, 269]. The beneficial effects of these agents might be through ameliorating injury pathways detailed earlier in this chapter, along with affecting recovery pathways. The basic science studies of stem cells in AKI are being translated into clinical studies. Thus far, phase 1 clinical trials using allogeneic MSC show that they are safe, but in a phase II trial there was no evidence of protection against AKI in patients undergoing on-pump cardiac surgery [270, 271].

Long-Term Sequelae

The focus in the clinical realm, and in experimental models of AKI, typically is on the severity of the acute renal manifestations and the speed and completeness of early recovery. Little attention is commonly given to long-term sequelae in the kidney following an episode of AKI, since most patients who survive the triggering event appear to recover renal function completely. Decades ago it was found that many adult patients who suffered from acute renal failure never recovered renal function completely, manifested by decrements in GFR and urinary concentrating ability months to years later [272–276]. Prior to 2003, these studies were few in number, examined relatively small sample sizes and with varying definitions for both AKI and progression. Potential causative links between AKI and chronic kidney disease (CKD) were not investigated and no serious consideration was given to understand long-term expectations or develop plans for management of patients following AKI.

However, in the last 15–20 years there has been a dramatic increase in research on the chronic effects of AKI [19, 277–280]. Recent studies using large databases have found significant correlation between AKI and progression to CKD and end-stage renal disease (ESRD) [281]. Meta-analysis found an 8.8-fold increase risk for CKD and a 3.3-fold increase risk for ESRD in surviving AKI patients after hospital discharge [282]. In addition, the finding of significant and progressive renal insufficiency in adolescence and early adulthood after recovery from AKI as a neonate is of particular interest. Though the neonatal kidney may be more resistant to AKI, it may be more prone to develop late sequelae once AKI has been established [19, 277–280].

The cause of progression to CKD following AKI is not clearly identified. Animal models indicate that there is a lack of fidelity in the repair responses following injury. Renal repair can be classified as either adaptive or maladaptive, and both may occur simultaneously. Maladaptive repair is the development of fibrosis in the tubular and interstitial compartments in response to acute kidney injury.

The underlying pathophysiology that predisposes to the development of CKD following AKI is not clearly defined, but has been subject to intensive investigation in recent years. Animal models of AKI with extended recovery from what was historically studied (months vs. days) suggest a lack of fidelity in the repair responses which fail to restore the kidney to its pristine, pre-injury state. These alterations may be the link between acute injury and subsequent development of CKD and hypertension [19]. An evolving view is that ineffective or maladaptive repair occurs in the tubular and interstitial compartments following AKI allowing for the development of interstitial fibrosis [283].

Several pathophysiological processes may contribute to maladaptive repair (see Fig. 6). Incomplete tubular repair following AKI leading to CKD has been a primary topic in the AKI-to-CKD transition. In severe cases, or following repeated insults, tubular repair may be absent leading to disconnection of intact glomeruli from residual tubule segments, with subsequent decline in overall renal function [284, 285]. However, incomplete repair may also manifest as persistent dedifferentiation of a subpopulation of tubule cells or as tubular cells that have initiated proliferation but become growth arrested in the G2 phase of the cell cycle. These cells are thought to produce profibrotic factors that stimulate the adjacent interstitium to develop fibrosis [286–288]. Epigenetic alterations during repair may facilitate these changes through histone modifications, DNA methylation, or chromosomal conformational changes that regulate gene expression. Histone deacetylase inhibitors accelerate recovery and decrease post-injury fibrosis after ischemia and reperfusion [289]. Single-nuclei RNAseq and advanced informatics have newly identified a population of cells that transform into what has been termed “failed-recovery proximal tubule cells” (FR-PTC). This small population of cells persists following AKI and have been found to have activated profibrotic and inflammatory pathways. A similar population of FR-PTC was identified in human kidney allografts [290].

In addition to altered tubules, reduction in capillary density is found following acute kidney injury in multiple animal models and in humans [291]. The reduction in renal capillary density is

Fig. 6 *Potential pathways from AKI through microvascular injury to chronic kidney disease (CKD).* Renal microvascular injury in AKI, in addition to extending the acute tubule injury, contributes to development of CKD through several possible mechanisms. Microvascular injury triggers inflammation with increase in pro-fibrotic cytokines and inhibition of vascular repair. Subsequent microvascular dropout can contribute to ongoing local hypoxia. Chronic hypoxia along with endothelial-mesenchymal transition (EndoMT) may then promote interstitial fibrosis. (From Ref. [19])

thought to contribute to local hypoxia, which is considered a major stimulus driving interstitial fibrosis [291]. Thus, strategies to mitigate renal vascular loss or local hypoxia might prevent progressive CKD following an episode of AKI. Renal vascular loss is associated with a reduction of renal VEGF expression, and exogenous VEGF-121 supplementation preserves capillary density and mitigates progression to CKD in rats [43, 292]. The capillaries of the kidney appear to have limited repair potential, and the ability to reverse established rarefaction is not well described [293]. Nevertheless, the use of novel VEGF-derived chimeric proteins, myeloid-derived-angiogenic cells, or endothelial colony-forming cells might lead to enhancing renal vascular recovery [67, 294].

In the absence of vascular repair, renal vasodilators might reduce hypoxia and prevent CKD progression. For example, administration of L-arginine postischemia improved chronic renal blood flow, limited hypoxia, and prevented CKD progression without restoring capillary density [43]. Another potential strategy to prevent CKD after AKI is through activating intrinsic defensive mechanisms against hypoxia and oxidative stress. HIF activation prior to induction of AKI lessens the acute injury and prevents the later development of fibrosis [295, 296]. Pharmacological Nrf2 activation induces antioxidative genes and ameliorates AKI in mice [297, 298]. Although promising, it remains to be determined whether Nrf2 activation can prevent the transition of AKI to CKD.

Fibroblasts, myofibroblasts, and the persistent influence of inflammatory macrophages and lymphocytes contribute to late alterations in the interstitial compartment after AKI [288]. The expansion of the interstitial space appears to follow several processes: pericyte activation and conversion into a myofibroblast-like state [299], invasion of fibrocytes [300], and endothelial-mesenchymal cell transition [291]. Fibroblasts and myofibroblasts are considered the primary cells responsible for interstitial scar formation. Persistent oxidative stress or the production of profibrotic factors (e.g., TGF-β, CTGF, and PDGF-B) derived from either damaged PTCs, FR- PTC, or infiltrating macrophages or lymphocytes may promote progressive interstitial fibrosis [288, 301]. Strategies to block chronic macrophage responses can block progressive kidney disease following AKI [302]. In addition, persistent lymphocyte expression, particularly T helper 17 cells, has been shown during CKD progression following AKI. Inhibition of lymphocytes with mycophenolate attenuates the transition to CKD following ischemia-induced AKI in rats [303].

Conclusion

The study of acute kidney injury that leads to clinical acute renal failure continues to advance. The progressive discovery of the many facets in the pathogenesis of the injury, markers of the injury, and potential recovery mechanisms provides hope that therapy targeted to the kidney injury specifically, along with ongoing advances in supportive therapy, will substantially improve survival and wellness of patients affected by acute kidney injury. Suggested by the many interactive pathways in AKI outlined here, both for ischemia- and sepsis-induced AKI, no single intervention alone is likely to alter outcome substantially. An integrated approach may be required to limit injury or facilitate renal recovery. Having a clear understanding of the pathogenesis of acute kidney injury from a particular renal insult should help direct when to intervene with a specific therapy, and which intervention would be most likely to benefit the patient.

Abstract

Critically ill neonates are at risk for acute kidney injury (AKI) and associated complications including fluid overload, longer mechanical ventilation time, increased hospital length of stay, and death. While the general approach to the evaluation and management of AKI in babies is similar to that in older children and adults, optimal care of these fragile patients requires an understanding of the aspects of neonatal physiology and disease unique to this patient group. Neonatal-specific high risk-conditions include extreme prematurity, perinatal asphyxia, necrotizing enterocolitis, and hemodynamically significant patent ductus arteriosus. In addition, neonates exhibit a renal physiology that changes as they transition from intra- to extra-uterine life, one that varies also between term and preterm infants, and creates challenges for interpretation of kidney function biomarkers such as serum creatinine and urine output. Patient heterogeneity in terms of gestational age and size poses additional challenges for the standardization of AKI definitions and monitoring as well as for provision of kidney support therapy when needed. Medical management has historically been the cornerstone of therapy due to technical barriers associated with providing kidney support therapy to these small patients, but advances in technology are reshaping the indications, timing, and risks and benefits of dialysis provision in this setting. New research is highlighting the interplay between AKI and other organs, especially the lungs and brain. The risk for chronic kidney disease, especially in extremely premature infants with and without a history of AKI, is becoming increasingly clear and highlights the need for long-term follow-up.

Acute kidney injury, acute renal failure; Kidney support therapy, renal replacement therapy; Newborn, neonates

Introduction

Critically ill newborns are at risk for acute kidney injury (AKI) and related complications including morbidity, mortality, and increased hospital length of stay, similar to older patients. While some of the causes of AKI are the same in neonates as they are in older children and adults (e.g., hypotension, sepsis, medication nephrotoxicity), other high-risk conditions and differing pathophysiology are unique to this patient group. In addition, the diagnosis of AKI in neonates using standard AKI biomarkers and definitions is made more challenging by the unique neonatal renal physiology during the first week of life. Moreover, the wide range in gestational age (GA) and size – from extreme prematurity at 22 weeks gestation to term infants at 40+ weeks – creates significant heterogeneity within the neonatal intensive care unit (NICU)population. The extremes in gestational age and size create challenges for the use of kidney Replacement therapies (KRT), most of which have been designed and sized for adults but only adapted for children, when necessary. In this chapter, we provide an overview of the evaluation and management of AKI in neonates including discussion of mechanisms and high-risk conditions, strengths, and limitations of available kidney function biomarkers, medical management strategies, and KRT options.

Acute Kidney Injury in the NICU: Scope of the Problem

Both single-center and a large multicenter cohort studies have demonstrated that AKI is common in critically ill neonates, ranging from 30% to 40% depending on the sample and associated comorbidities [1–3]. In addition, neonates with AKI have higher mortality rates than those without AKI. A large multinational, multicenter study of neonates, the Assessment of Worldwide Acute Kidney Injury Epidemiology in Neonates (AWAKEN) showed an overall AKI incidence of 30%, with a U-shaped distribution according to GA (37% in term infants, 18% in 29–36 weeks, and 48% in <29 weeks GA) [1]. Other samples from developing countries show similarly high rates of AKI incidence and associated mortality. Mwamanenge [3] identified an AKI rate of 31.5% in their cohort from Tanzania where AKI was primarily related to sepsis, pneumonia and use of gentamicin. In the AWAKEN study, two-thirds of the AKI events happened early in the course (first postnatal week), with the other 1/3 happening after 7 days of life [4, 5]. Importantly, 28% of those babies who had an early AKI event had at least one additional AKI episode later in the hospital course.

AKI Definitions and Biomarkers

The AKI definition for neonates remains an area of ongoing research and debate. Standardized AKI definitions have been derived from adult data and extrapolated for use in children and infants. Some of the variability in the rates of AKI reported in neonatal studies is attributable to the variety of AKI definitions used, ranging from arbitrary cut-offs (e.g., serum creatinine ≥1.5 mg/dL) to categorical frameworks defining incremental increases in serum creatinine and decreases in urine output from established baselines. The most widely accepted definition currently is a modification of the Kidney Disease: Improving Global Outcomes (KDIGO) definition of AKI [6] (Table 1).

The challenge of establishing an AKI definition for neonatal cohorts is related to the unique renal physiology of neonates, especially in the first week of life when neonates are in a relative polyuric state. As mentioned above, kidney function in neonates undergoes dynamic change following birth. Cardiac output and resultant renal blood flow increase rapidly over the first days and weeks of life. Glomerular filtration rate (GFR) in the term infant increases from 10–40 ml/min/1.73 m^2 in the first 1–2 weeks of life to the expected adult GFR 100–120 ml/min/1.73 m^2 by

Table 1 Modified KDIGO AKI definition for neonates [6]

Stage	Serum creatinine (SCr)	Urine output (UOP)[a]
0	No change in SCr or rise <0.3 mg/dL	>1 mL/kg/h
1	SCr rise >0.3 mg/dL within 48 h *or* SCr rise ≥1.5–1.9 × rise from baseline (previous lowest value) within 7 days	> 0.5 and ≤ 1 mL/kg/h
2	SCr rise ≥2–2.9 × rise from baseline	> 0.3 and ≤ 0.5 mL/kg/h
3	SCr rise ≥3 × rise from baseline *or* SCr ≥ 2.5 mg/dL *or* KRT initiation	≤ 0.3 mL/kg/h

[a] For 24 h period

age 2 years [7]. This change occurs more slowly in preterm infants. Serum creatinine values, initially reflective of maternal levels, are therefore expected to decline over the first week(s) of life rather than remain in a steady state, making the application of standard AKI definitions problematic. In addition, early transient increases in serum creatinine may also be expected, especially in preterm infants, due to avid reabsorption of creatinine [8]. Some authors have proposed using absolute serum creatinine increases (e.g., >0.3 mg/dL) that vary by gestational age [9], while others have advocated using the rate of serum creatinine decline over the first week as an indication of impaired kidney function [10].

Oliguria, while recognized as an important and often under-recognized marker of AKI [11], is similarly difficult to utilize as a marker of AKI in the newborn. Babies undergo an obligate diuresis following birth. Urinary concentrating ability, especially in preterm infants, is immature such that neonates may sustain an AKI event while maintaining urine output above traditional AKI thresholds (e.g., <0.5 ml/kg/h). A higher urine output threshold <1.5 ml/kg/h has been evaluated as a reasonable predictor of mortality in one NICU cohort [12].

In addition to these limitations of serum creatinine and urine output for diagnosing AKI in neonates, they are also imprecise in their ability to distinguish functional changes from evidence of true injury/damage and to identify AKI early enough to intervene [13]. Thus, other kidney biomarkers are being evaluated in neonatal cohorts. Cystatin C (CysC), for example, is a cysteine protease inhibitor produced by all nucleated cells, is freely filtered by the glomerulus, and completely reabsorbed and catabolized by the proximal tubule [14, 15]. Because levels are not affected by hydration status, diet, or gender, both urine and serum CysC have been evaluated for their ability to identify AKI more reliably than serum creatinine, including in studies of term and preterm neonates [16, 17]. Other novel urinary biomarkers are under investigation in neonates, but not yet ready for broad clinical use. Importantly for neonates, the establishment of reference ranges is critical as levels vary by gestational age, postnatal age, sex, and birthweight [13, 18, 19].

Urine output response to a single dose of furosemide has been evaluated as a functional biomarker in critically ill adults, showing ability to predict progression to AKI stage 3 (“furosemide stress test”) [20]. Furosemide reaches the loop of Henle via tubular secretion and thus should have decreased efficacy in patients with AKI. Urinary response to furosemide has been evaluated in neonates undergoing cardiac surgery [21, 22]. In one study, a urine output response of >1 ml/kg/h following a single dose of furosemide (0.8–1.2 mg/kg between 8 and 24 h after surgery) identified those babies who were unlikely to go on to develop postoperative AKI (negative predictive value, 97%) [21].

Because of limitations of kidney function biomarkers in neonates, awareness of high-risk conditions is critical for detecting AKI early and preventing AKI-related complications. As mentioned above, many mechanisms of injury are the same in neonates as in older patients, but there are important conditions specific to this patient group. Some of the more well studied in terms of their association with AKI are described below.

High Risk Conditions

Prematurity and Low Birth Weight (LBW)

Babies born prematurely deliver prior to the completion of nephrogenesis, a process that typically occurs from 5–8 weeks to 34–36 weeks gestation, with the majority of nephrons forming in the third trimester [23]. Thus, these infants are born with less nephron endowment and with nephrons that are abnormal in structure and function. Autopsy studies of premature kidneys show that nephrogenesis continues briefly in the newborn period, but the nephron layers that are laid down are abnormal and at risk for additional injury [24, 25]. Decreased nephron mass plays an important role not only in AKI, but in long-term kidney health as well.

Single center data confirm that very low birth weight (VLBW) babies are at risk for AKI, and those with AKI have higher risk for mortality [2, 26, 27]. An ancillary study of the large multicenter Pre-term Erythropoietin Neuroprotection Trial (PENUT) evaluated 942 extremely premature infants <28 weeks GA to describe the epidemiology of AKI, relevant AKI outcomes and progression to CKD in population. This Recombinant Erythropoietin for Protection of Infant Renal Disease study (REPAIReD) also demonstrated AKI rates *increased* with *decreasing* gestational age and lower birthweight [2]. Indeed, lower gestational age and birthweight are frequently identified risk factors for higher rates of AKI across studies [28–30]. Other risk factors in this group include hemodynamically significant patent ductus arteriosus (hs-PDA) and necrotizing enterocolitis (NEC), higher severity of illness scores, and early symptomatic hypotension requiring volume resuscitation and/or pressor support [4, 28].

Term Infants

Term infants are also at risk for AKI. Thirty-seven percent of neonates with AKI in AWAKEN were in the ≥36 weeks GA group, a lower rate than in the extremely premature group (52% in <29 weeks GA), but higher than in the middle group (18.% in 29–26 weeks GA) [1]. Similar rates (35% and 46% depending on the AKI definition used) were documented in a sample of 80 infants (median GA 38 weeks) admitted to a pediatric intensive care unit either from home or the NICU [31]. Factors associated with AKI in this sample included younger age (median 3 vs. 12 days), higher serum sodium concentrations prior to AKI, diagnosis of persistent pulmonary hypertension (PPHN), history of umbilical catheters, bacteremia, transfer from the NICU, and support with extracorporeal membrane oxygenation (ECMO).

Perinatal Asphyxia and Hypoxic-Ischemic Encephalopathy (HIE)

Neonatal hypoxic-ischemic encephalopathy (HIE) occurs secondary to a period of inadequate cerebral blood flow and oxygen delivery, either in utero or in the perinatal period, as the result of compromised placental or pulmonary gas exchange [32]. In addition to cerebral injury, babies with perinatal asphyxia are at risk for multiorgan dysfunction. Improvements in both survival and neurodevelopmental outcomes have come about with the use of therapeutic hypothermia (whole body cooling) for infants 36 weeks gestational age and above [33].

Neonatal AKI is well documented in this setting [34–37]. Possible mechanisms include ischemia-reperfusion injury, other underlying comorbidities such as sepsis, and use of nephrotoxic medications [32]. Several studies document an association between AKI and higher rates of morbidity, mortality, and hospital length of stay in this setting. Moreover, worse neurodevelopmental outcomes have also been associated with the occurrence of AKI [35, 36]. In terms of AKI mitigation, several studies have examined the protective effects of methylxanthines (theophylline and aminophylline) in babies with perinatal asphyxia and are discussed further below. Therapeutic hypothermia has not been examined specifically as a kidney-protective strategy and is now standard of care in high-resource settings.

Necrotizing Enterocolitis (NEC)

Necrotizing enterocolitis (NEC) is a life-threatening, inflammatory intestinal condition that occurs in premature infants [38]. NEC is associated with AKI for multiple reasons including the underlying severe systemic inflammatory response, sepsis, and hypotension [28, 39–41]. AKI rates are high in these patients, reaching >50% in some studies [28, 40]. Babies with NEC and AKI have higher mortality rates than babies with NEC who do not develop AKI. These critically ill infants require broad spectrum, empiric antimicrobial coverage to cover for pathogens associated with late-onset sepsis and for anaerobic infections that occur as the result of intestinal perforation, adding to the AKI risk. These babies require careful kidney function, antibiotic level, and fluid balance monitoring.

Patent Ductus Arteriosus (PDA)

The ductus arteriosus plays a central role in fetal circulation in utero, connecting the main pulmonary artery to the descending aorta and allowing blood to bypass the fetal lungs. High circulating levels of prostaglandin E2 (PGE_2) promote smooth muscle relaxation and maintain the patency of the ductus. In full-term infants, the ductus arteriosus closes within a few hours after birth, but in premature infants this process may be delayed [42]. Depending on the size of the ductus, the PDA may become hemodynamically significant (hs-PDA), shunting blood away from systemic circulation, compromising perfusion to the gut and kidneys, and leading to pulmonary hypertension and right heart failure [43]. In addition to hypoperfusion-related AKI, a hs-PDA may be associated with adverse outcomes including bronchopulmonary dysplasia, pulmonary hemorrhage, NEC, intraventricular hemorrhage (IVH), and poor neurodevelopmental outcomes [42]. Treatment of the hs-PDA includes both medical and surgical options. Medical management is aimed at lowering PGE_2 levels such as with the use of nonsteroidal anti-inflammatory drugs (NSAIDS) like indomethacin and ibuprofen. AKI may arise as the result of hemodynamic changes and impact on renal perfusion, the vasoconstriction, and impact on renal blood flow of the NSAIDs. Because of the known potential nephrotoxicity of NSAIDs, alternatives such as acetaminophen/paracetamol have been evaluated, with some evidence showing similar efficacy in ductal closure rates and fewer side effects using this therapy compared with traditional indomethacin [44]. Management decisions regarding timing and appropriate treatment for hs-PDAs present clinical challenges for the medical team [45].

Congenital Heart Disease and Cardiac Surgery-Associated AKI (cs-AKI)

The occurrence of AKI in babies undergoing surgery for congenital heart disease (cs-AKI) is well documented [21, 29, 30, 46, 47]. Risk factors include lower age and weight at the time of surgery, higher surgical complexity scores, longer cardiopulmonary bypass, and cross-clamp times [21, 22, 29, 30, 46]. As in other patient groups, AKI in this setting is associated with worse outcomes including longer length of stay, longer time to extubation, more ventricular dysfunction, need for ECMO, and higher rates of mortality [30, 46]. The occurrence of cs-AKI also has been linked with the development of chronic kidney disease (CKD) [29]. Since the timing of the kidney insult(s) (e.g., inflammation associated with cardiac bypass, intraoperative hypotension, ischemia-reperfusion injury) related to cardiac surgery is known, it is reasonable to consider options for AKI therapeutic interventions in this context. Several therapies including corticosteroids, dexmedetomidine (a selective α2-agonist that may attenuate inflammation and subsequent ischemia-reperfusion injury), fenoldopam (a selective dopamine-1 receptor agonist that increases renal blood flow through vasodilation of renal and splanchnic vasculature), acetaminophen, and aminophylline have been evaluated as preventive measures, but none have demonstrated clear efficacy in their ability to prevent cs-AKI [48].

Congenital Diaphragmatic Hernia (CDH)

Congenital diaphragmatic hernia (CDH) is a defect that allows abdominal contents to enter the chest cavity leading to variable degrees of pulmonary hypoplasia and pulmonary hypertension. Many of these infants are critically ill at birth, requiring initial support with extracorporeal membrane oxygenation (ECMO). Not surprisingly, this condition has also been associated with high rates of AKI, with reported rates ranging from 37% in all infants with CDH to 71% in those requiring ECMO support [49–51]. AKI in this context is also associated with higher mortality rates.

Extracorporeal Membrane Oxygenation (ECMO)

Extracorporeal membrane oxygenation (ECMO) is a form of advanced mechanical life support for patients with severe but reversible forms of respiratory and cardiac failure refractory to conventional management. High rates of AKI have been documented in critically ill neonates requiring support with this therapy [50, 52, 53]. Patients on ECMO who develop AKI have a longer ECMO duration [52] and higher rates of mortality, with risk of mortality increasing with increasing AKI severity [50]. AKI appears to happen early in the ECMO course, often within the first 48 h of therapy initiation. Neonates supported with ECMO have many potential AKI risk factors including hemodynamic instability, multiorgan failure, hypoxia/asphyxia, sepsis, and shock that occur both prior to and during the ECMO run, and it has been suggested that the ECMO circuit itself may play a role in the inflammatory response [50, 52, 54].

Surgical Procedures

Admission with need for a surgical procedure was identified as a risk factor for both early and late AKI in the AWAKEN cohort, though AWAKEN study did not examine the temporal relationship between the procedure and the AKI event [4, 5]. A retrospective study of 160 neonates by Wu et al. [55] identified AKI following surgical procedures in 33.8% of the sample. AKI was associated with higher rates of mortality, with increasing mortality rates associated with greater severity of AKI events (stage 1–9.7%, stage 2–23.1%, and stage 3–40% mortality). Longer operative time (>120 min), lower gestational age and birthweight, sepsis, and diagnosis of necrotizing enterocolitis were all associated with AKI development. Median time to diagnosis of AKI was 38.5 h after the surgery or within 23 h for patients with sepsis.

Mechanisms

Medication-Induced AKI

Many of the medications used in the NICU to treat the conditions described above have nephrotoxic potential. Indeed, exposure to nephrotoxic medications is widespread, with over 80% of premature infants receiving at least one nephrotoxic medication during their NICU stay [56, 57]. There is not always a reasonable, non-nephrotoxic alternative to some of these medications, and whether the AKI that occurs in these settings is related to the underlying condition, the nephrotoxic medication, or a combination is not always clear. How to balance the risks and benefits of treating the condition with the AKI risks associated with the treatment itself continues to be a significant challenge for the teams caring for these infants [45]. Understanding the mechanism of injury from both the underlying condition and the medications is important for developing effective AKI monitoring and mitigation strategies. Table 2 includes a summary of medications commonly used in the NICU and their mechanisms of injury.

Vascular/Ischemic Injury

Renal Vascular Thrombosis

With a combination of lower renal perfusion pressure and blood flow, small renal vessel diameter, and susceptibility of the neonatal hemostatic system to imbalance, neonates carry a high risk for thromboembolic complications involving the renal vasculature [58]. Many conditions that occur during the perinatal period are risk factors for renal vascular thrombosis, including perinatal asphyxia, volume depletion, hypotension, placement of indwelling catheters, polycythemia, and activation of the renin-angiotensin-aldosterone system (leading to vasoconstriction). Additionally, maternal factors such as preeclampsia, diabetes, and autoimmunity have also been associated with these events [59]. Cases of renal arterial thrombosis (RAT) have been associated with arterial catheters (especially when placed for prolonged periods), prematurity, low birth weight, sepsis, and retinopathy of prematurity [60]. Renal vein thrombosis (RVT) is much more common than RAT, though neither occur with great frequency. RVT seems to present more frequently in males and is more commonly unilateral, and with the classic triad of gross hematuria, palpable flank mass, and

Table 2 Commonly used medications in the NICU associated with AKI

Drug name	Mechanism of action	Mechanism of injury
Acyclovir	Antiviral therapy that works by inhibiting virus DNA polymerase, which stops the spread of HSV in the body. Acyclovir has activity against HSV, VZV, and EBV	Tubular damage through crystallization and obstruction especially with low urinary flow
Amphotericin B deoxycholate (conventional)	Disrupts fungal cell wall synthesis by binding to ergosterol, leading to formation of pores that leak cellular components	Direct distal tubular toxicity and vasoconstriction. Signs of nephrotoxicity include hypokalemia, hyponatremia, metabolic acidosis, and hypomagnesemia as well as elevated serum creatinine
Gentamicin	Aminoglycoside that interferes with bacterial protein synthesis by binding to 30S ribosomal subunit resulting in a defective bacterial cell membrane	High binding affinity for the proximal tubular brush border membrane via the megalin complex. Signs of nephrotoxicity include electrolyte wasting but not usually a change in urine output. Alterations in kinetics seen in the setting of HIE [37]
Indomethacin	Nonselective COX inhibitor decreasing synthesis of prostaglandins which causes vasoconstriction and subsequent closing of PDA	Causes afferent arteriole vasoconstriction and reduced GFR
Piperacillin-Tazobactam	Inhibits bacterial cell wall synthesis, eventually leading to bacteria lysis	Piperacillin inhibits tubular secretion and clearance. Piperacillin and vancomycin combined may cause direct toxicity of proximal tubule cells
Vancomycin	Bactericidal glycopeptide that disrupts cell wall synthesis of Gram-positive bacteria	Unclear: piperacillin and vancomycin combined may cause direct toxicity of proximal tubule cells

thrombocytopenia (though only a small fraction of cases with all three) [59]. RAT may be diagnosed during the work-up for neonatal hypertension. Diagnosis is confirmed with imaging such as ultrasound with Doppler. Findings suggestive of RVT include enlarged and echogenic kidneys with loss of corticomedullary differentiation and increased resistance in the renal arteries. The thrombus may extend into the inferior vena cava. Treatment may include heparin to prevent thrombus extension as well as thrombolytic agents in cases of more severe thrombus. While these RVTs may not be life-threatening, the majority result in some degree of permanent kidney injury (e.g., kidney atrophy) with resulting CKD in up to a third and end-stage kidney disease (ESKD) in some even with treatment [59].

Twin-to-Twin Transfusion Injury

Twin-to-twin transfusion syndrome (TTTS) is a rare disorder estimated to affect 10–20% of monochorionic twin gestations [61]. This serious condition occurs when there is unequal distribution of placental blood supply via shared vascular anastomoses and results in asymmetric fetal growth, postnatal morbidity including cerebral injury and respiratory distress syndrome, and mortality [61]. Twins are characterized as either the donor or recipient twin depending on the direction of the transfusion of blood from one to the other. AKI is well described as the donor twin experiences hypovolemia and hypotension-related ischemic injury. Advanced CKD/ESKD may also occur [62].

Renal Cortical Necrosis

Renal cortical necrosis is another rare but serious and irreversible condition that occurs as the result of profound ischemic injury. Catastrophic perinatal complications like placental abruption, congenital heart disease, and severe perinatal asphyxia occur during a critical period of change in renal blood flow with the transition to extrauterine life and put neonates at high risk for this event [63, 64]. Obstetrical emergencies that put both mother and baby at risk for AKI and renal cortical necrosis continue to be a clinical concern, especially in developing countries [63, 65], though the overall incidence of such events is declining.

Evaluation

History

Evaluation for AKI starts with a careful history searching for any of the events described above; more than one of these conditions may often be present. The prenatal course should be reviewed for reports of abnormal prenatal ultrasound findings (e.g., congenital anomalies of kidney and urinary tract (CAKUT), abnormal amniotic fluid levels), maternal medicine use (e.g., ACE-inhibitors, illicit drug use), perinatal complications suggesting fetal compromise including nonreassuring fetal status, placental abruption, maternal hemorrhage, pre-eclampsia/eclampsia, and intrauterine growth restriction. The delivery room course should be reviewed for the type of resuscitation needed as well as the time required to achieve stabilization. Delivery outside, and transfer to a tertiary healthcare setting (outborn delivery), has been associated with AKI in the first week of life [4]. Maternal factors such as receipt of steroids, hypertension/preeclampsia, and receipt of magnesium have been associated with lower incidence of AKI in the baby [4, 5, 28].

Physical Examination

The physical examination is critical for assessment of both volume and hemodynamic status. A primary goal of management is to ensure optimal renal perfusion as well as to prevent the consequences of fluid overload. Often the conditions described above (e.g., hs-PDA, perinatal asphyxia, NEC) are associated with hemodynamic imbalance that requires understanding of neonatal cardiovascular function and therapeutic intervention targeted at the disease pathophysiology in collaboration with the neonatology team [43].

Fluid Balance

Neonates are expected to undergo an obligatory diuresis during the first 10 days of life. Failure to do so, such as with the use of inappropriately high fluid intakes or in the setting of AKI, has been associated with increased risk of PDA [66], NEC [67], bronchopulmonary dysplasia [68], and prolonged mechanical ventilation. Achieving a negative fluid balance by postnatal day 7 has been associated with decreased risk for mechanical ventilation by that day in both preterm and term cohorts [69, 70]. As it has in older children and adults, fluid overload (FO) $>$ 10% in certain subgroups of neonates has been associated with worse outcomes, both in conjunction with and independent of diagnosed AKI [54, 71].

Early identification and management of FO is thus an important part of the evaluation and management of high-risk neonates, though critically ill infants are also at risk for complications related to volume depletion. While estimation of fluid balance is a focus of care, accurately determining the volume status of these babies can be difficult based on physical exam alone. Both weight-based [e.g., % weight change = (daily weight − birthweight)/birthweight × 100] and intake/output-based [e.g., % weight change = (intake − output from time of ICU admit)/admit weight × 100] formulas have been used for estimating cumulative fluid overload in neonatal and pediatric cohorts [72]. In addition, all fluid intake and loss should be reviewed. Even small volumes received via flushes and intermittently dosed medications may impact overall fluid balance, especially for premature and LBW infants. Common sources of losses for critically ill babies are described in Table 3. Some of these losses may be difficult to measure accurately. In addition, babies often do not have urinary catheters in place as a policy reduces infection risk. Urine output may be captured under “urine/stool mix” and may thus be hard to quantify. Good communication with bedside staff is critical. While urine output is often a

Table 3 Common AKI etiologies and risk factors in newborns

High risk conditions
Prematurity and low birth weight
Hemodynamically-significant PDA
Necrotizing enterocolitis
Perinatal asphyxia
Congenital diaphragmatic hernia
Support with ECMO
Need for surgical procedures (cardiac, thoracic, abdominal)
Outborn delivery
Treatment with ≥ 3 potentially nephrotoxic medications
Fluid loss and volume depletion
Gastrointestinal losses (emesis, diarrhea, NG, and enteral tube output)
Poor oral intake
Fluid losses from chest tubes, ventricular, and other drains
Excessive diuretic use
Congenital kidney disease with associated concentrating defects (e.g., dysplasia)
Polyuria following relief of urinary tract obstruction (“postobstructive diuresis”)
Inadequate renal perfusion
Congestive heart failure
Coarctation of the aorta
Treatment with ACE-inhibitors or NSAIDs
Hypoalbuminemia and low oncotic pressure
Increased abdominal pressure (e.g., with necrotizing enterocolitis)
Ischemic/vascular
Hemorrhage of any cause
Renal vessel thrombosis
Placental abruption/maternal hemorrhage
Twin-twin transfusion
Obstructive
Congenital malformations (posterior urethral valves, urethral stricture, neurogenic bladder)
Occluded urinary catheter
Medication-related urinary retention
Sepsis and other infections
Bacteremia, pyelonephritis, meningitis, congenital infections

PDA patent ductus arteriosus, *ECMO* extracorporeal membrane oxygenation, *NG* nasogastric, *ACE* angiotensin converting enzyme, *NSAIDs* nonsteroidal anti-inflammatory drugs

good marker of volume status, the kidneys of premature infants lack mature urinary concentrating ability and may have seemingly good urine output even in the context of volume depletion.

Other Innovations in Neonatal Intensive Care

Many of the conditions described above result in AKI because of hemodynamic instability and decreased renal blood flow. Given the limitations of kidney function biomarkers, use of other techniques to assess systemic and kidney perfusion could aid in the detection of at-risk neonates and help elucidate the underlying pathophysiology. Near-infrared spectroscopy (NIRS) provides a noninvasive, continuous method to monitor regional oxygenation in cerebral or somatic tissues, measuring oxygen saturation of hemoglobin in the sampling volume comprising venous, capillary, and arterial blood. NIRS is finding increasing use in NICUs for monitoring the kidney and in research studies as a tool for the early detection of AKI across a variety of settings in both term and preterm neonates [73, 74]. Changes in tissue oxygenation can identify renal hypoperfusion and hypoxia that may herald the development of AKI prior to changes in serum creatinine or urine output. Targeted neonatal echocardiography

(TnECHO) is another recent innovation being implemented in some centers [43]. The goal of TnECHO is to monitor changes in cardiac function and systemic perfusion in different disease states, guide appropriate vasoactive therapy, and assess response to therapeutic interventions. Optimization of hemodynamic status should benefit kidney function, though TnECHO has not been studied directly as an AKI prevention or mitigation tool.

Management

AKI Identification, Mitigation, and Prevention

Despite major advancements in our understanding of neonatal AKI, we still lack effective treatment strategies for this syndrome. Thus, current AKI care involves surveillance, early recognition, and prevention where feasible. Several awareness and intervention bundles have been developed in pediatric and adult cohorts [75–77], showing efficacy in improving identification and documentation rates of AKI events but not yet in reducing mortality [75]. An AKI bundle proposed for neonatal cohorts [78] is listed in Table 4. Increasing the frequency with which kidney function is monitored and documented in NICU is an important step in identifying AKI in these babies and ensuring appropriate follow-up [79, 80].

Table 4 Proposed neonatal care bundle to guide the evaluation and management of modifiable risk factors and complications of AKI

Monitor volume intake/output and daily weights
Calculate cumulative fluid balance and degree of fluid overload
Review medication list for potentially nephrotoxic medications and need for dosing adjustments based on GFR
Evaluate for underlying AKI cause/physiology
Treat hypotension, hypoperfusion, hypoalbuminemia, high abdominal pressure, and urinary tract obstruction
Evaluate nutrition and electrolyte composition of fluid intakes
Engage multidisciplinary team: pharmacy, dietitian, bedside nurses, family

Medical Management of AKI Complications

Given the complexities of using KRT devices in small babies, awareness of available medical management options is an important part of care.

Electrolyte and Mineral Homeostasis

Neonates with AKI may be at risk for a variety of electrolyte abnormalities depending on the mechanism and severity of injury. For example, babies with gentamicin toxicity may maintain urine output but have elevated serum creatinine, hypokalemia, and hypomagnesemia secondary to tubular injury. Babies with severe oligo-anuric injury may develop hyponatremia secondary to fluid overload and/or severe hyperkalemia and hyperphosphatemia.

Hyperkalemia is a potentially life-threatening manifestation of AKI. In babies with oliguria and rising serum potassium levels, all fluids should be reviewed and adjusted for potassium content. Enteral feeds may need to be adjusted to lower-potassium formulations. Breast milk is an excellent choice due to low solute load and appropriate balance of nutrition. Potassium levels can be decreased also through urinary (e.g., with diuretics) or gastrointestinal excretion (e.g., with cation exchange resin), or via dialysis. Shifting potassium from the extracellular to intracellular compartments can be accomplished through use of base supplementation (sodium bicarbonate or acetate) to change pH, albuterol, and/or insulin and glucose. Serious adverse events including colonic necrosis and death have been described when cation exchange resins are given to babies directly [81]. To avoid direct administration, methods for pretreating infant formula with cation exchange resins have been published. Importantly, pretreating infant formula and breast milk alters the nutrient content, *decreasing* calcium and magnesium content and *increasing* sodium content [82, 83].

Infants with AKI may develop either hyponatremia or hypernatremia depending on the situation. Hyponatremia may develop as the result of total body fluid overload or as the result of sodium losses through chest tubes or gastrointestinal suction or through urinary sodium wasting in infants with congenital kidney and urinary tract disease (e.g., dysplasia, obstructive nephropathy). Fluid balance assessment and clinical context will guide appropriate management (fluid restriction vs. provision of sodium supplementation). Infants may also be at risk for hypernatremia as the result of large insensible losses (e.g., extremely premature infants with immature skin barrier), immature urinary concentrating ability, or large sodium intakes. Again, careful assessment of fluid balance and composition and volume of fluid inputs is important for determining appropriate response (e.g., provision of free water or increase in basal rate of fluids).

Infants with AKI may develop hyperphosphatemia due to impaired renal phosphorus excretion. Concentrated preterm formulas and human milk fortifier are especially high in calcium and phosphorus to promote bone health in premature infants as human milk is naturally low in all solutes [84]. Collaboration with a neonatology dietitian will allow for optimal adjustment of enteral nutrition if required for a more severe and extended episode of AKI. As with hyperkalemia, enteral nutrition may be pretreated with a phosphate-binding agent that decreases the phosphorus content of the feeds before they are given to the baby. Sevelamer is a noncalcium containing polymeric ion-exchange phosphate binder that has been studied in this setting [83, 85, 86]. As with ion exchange resins, pretreatment of enteral formula with sevelamer may decrease the calcium content. Calcium carbonate comes in a liquid formulation and is another enteral option.

Acid-Base Balance

Metabolic acidosis is a potential complication of neonatal AKI as the result of the underlying mechanism of the injury (e.g., large volume stool losses/diarrhea, poor systemic perfusion from sepsis or heart failure) or from impairment in excretion of acid as the result of decreased GFR. In addition, the immature tubular function of premature infants may result in urinary bicarbonate losses even without overlying AKI. Base supplementation may be required and can be given as either sodium bicarbonate or sodium acetate.

Therapeutics

Methylxanthines (Theophylline, Aminophylline, and Caffeine)

Theophylline and Aminophylline in Babies with Perinatal Asphyxia

Animal models and human studies demonstrate an increase in renal adenosine levels in states of acute renal hypoxemia and ischemia that then lead to renal vasoconstriction, decreased GFR, and a fall in urine output [87, 88]. These events serve as the rationale for the use of theophylline, an adenosine receptor antagonist, in the prevention of AKI in asphyxiated neonates. A single dose of theophylline (either 5 or 8 mg/kg) within 6 h of birth in these high-risk babies promotes improved urine output, lower serum creatinine rise, more favorable fluid balance, and less tubular injury [89]. The therapeutic effect appears to be most pronounced on days 3 and 5. All but one study of theophylline was completed in cohorts of term and postterm infants. Moreover, all were completed in centers without whole-body cooling. Aminophylline, a related salt of theophylline with the same active molecule, has also been evaluated in a small retrospective cohort of neonates who were cooled for moderate/severe HIE [90]. Treated infants who survived had improved urine output and decline in serum creatinine within 12 h of therapy, though the nonsurvivors in the treatment group did not show improvement in kidney function parameters.

Based on the currently available evidence, a single dose of theophylline within the first 6 h of life for newborns with perinatal asphyxia is endorsed in the KDIGO guidelines [91]. While the side effect profile of theophylline (seizures, arrhythmias, and gastrointestinal complications) is important, none of the above studies noted any difference in either mortality or adverse events between the treated and control groups. These findings should be confirmed in a larger, randomized controlled trial including in babies who are treated with whole body cooling.

Caffeine Use in Preterm Infants

Caffeine is an adenosine receptor antagonist that inhibits the preglomerular vasoconstrictive effects of adenosine and as such may be protective against AKI [92–94]. Two studies demonstrate AKI occurs less frequently in VLBW and preterm infants <33 weeks GA who received caffeine within the first week of life as compared to those who did not [93, 94]. In the first study by Carmody [93], the protective effect of caffeine against AKI appeared to be even stronger in the subgroup of babies who received prolonged mechanical ventilation. In a larger retrospective cohort (n = 675), Harer [94] showed babies who received caffeine had more AKI risk factors including lower average GA, lower birth weight, and higher severity of illness scores and were *still* less likely to develop stage 2 or 3 AKI. The role of caffeine in the mitigation of AKI in a cohort of neonates has also been documented in the setting of NEC with similar protective effects [92].

Diuretics

Diuretics are medications used to augment urine output in patients who have developed oliguria, though there is no evidence to support their use for the purpose of reversing the injury itself or improving outcomes [95]. They are widely used in the NICU, though with limited evidence to support their efficacy across clinical settings [96]. Awareness of their limitations as well as their side effects is important for rational and careful use of these medications. Loop diuretics act at the Na^+-K^+-$2Cl^-$ co-transporter in the thick ascending limb of the loop of Henle. Pharmacologic tolerance may occur with repeated doses as extracellular volume depletion associated with diuresis may trigger an increase in water and sodium reabsorption in other parts of the nephron (both proximal and distal tubules) [96, 97]. Side effects include hypotension, hypokalemia, and hypochloremic metabolic alkalosis as well as hypercalciuria that may lead to bone demineralization and nephrocalcinosis [98]. Ototoxicity is a rare complication that may occur with chronic use [99].

Thiazide diuretics act at the Na^+/Cl^- transporter in the distal tubule to promote water and sodium excretion. Thiazide diuretics are typically less potent than loop diuretics because less sodium is absorbed in this part of the nephron [96]. Unlike loop diuretics, thiazides promote calcium reabsorption in both the proximal and distal tubules [100] and may be protective against nephrocalcinosis.

Kidney Replacement Therapies (KRT)

Because of numerous technical challenges, the use of KRT in neonates historically has been considered a heroic intervention to be applied only when all other medical management has failed. Recent technological developments and the approval of extracorporeal blood purification devices designed specifically for babies have made KRT more feasible and will significantly alter the indications, timing of, modalities available for, and feasibility of KRT in these patients.

The use of peritoneal dialysis (PD), hemodialysis (HD), or extracorporeal continuous KRT (CKRT) depends on several factors including patient characteristics and hemodynamic stability, goals of therapy (fluid removal, electrolyte disorders, toxin removal), physician experience, and institutional resources. Each technique is associated with potential advantages and disadvantages; however, the optimal modality, dosing of, and timing for KRT initiation are unknown.

In general, the indications for KRT are the same in neonates as in older children. KRT should be applied to prevent further fluid accumulation, restore euvolemia, and metabolic balance, as well as to allow provision of adequate nutrition, blood products, and medications. Moreover, critically ill neonates with kidney dysfunction often have dysfunction in other organs as well. KRT can be initiated in situations where nonrenal conditions may lead to AKI, such as septic shock, cardiopulmonary bypass, inborn errors of metabolism, and hyperammonemia to improve outcomes.

Peritoneal Dialysis

PD has long been considered the modality of choice when treating neonates with AKI, including premature infants. It has a prominent role in the treatment of small infants after surgery for congenital heart defects [101]. Elective placement of a PD catheter at the time of surgery in infants determined to be at high risk for AKI is associated with shorter time to negative fluid balance and improved clinical outcomes as compared with age-matched infants undergoing similar surgery without PD catheter placement or use [102]. The popularity and success of PD for neonates is derived from its simplicity and effectiveness in even the smallest patients. This technique avoids the need for anticoagulation, provides excellent hemodynamic stability, and has a theoretical advantage in premature neonates related to the large peritoneal surface area-to-body ratio that provides improved dialysis efficacy. The lower dialysate fill volumes used for neonates generally necessitates the use of manual exchanges via commercially available two-chamber sets that allow inflow and outflow volumes to be measured with an accuracy of 1 ml. In this setting, dwell times are initially every 30–60 min provided continuously, a schedule that most often requires a one-to-one level of nursing support. To improve the efficacy of PD, some authors have suggested using continuous flow PD, but this requires two peritoneal catheters, or one double lumen catheter, instead of the usual one [103].

The most common issue in acute PD is the introduction of a suitable peritoneal catheter. With a need to start PD soon after catheter placement, there is an increased risk of catheter leak, infection, and mechanical complications [104, 105]. In term neonates, single-cuff straight (Tenckhoff®) catheters are available and are usually implanted with a paramedian entry-site. In some cases, the poorly represented peritoneal layer relative to the large caliber of the catheter and the internal cuff prevent a firm fixation of the catheter to the abdominal wall. In this case, fibrin glue (a mixture of fibrinogen and thrombin) can be applied on the external layer of the peritoneal membrane to produce a physiologic fibrin clot that may stop dialysate leakage, prevent infections, and eliminate the need for surgical interventions [106]. The fibrin clot then degrades over weeks by natural fibrinolysis.

Obtaining catheter access for PD is complicated in extremely or VLBW neonates by their small size and paucity of subcutaneous tissue. The distance between the umbilicus and the symphysis pubis in these patients is only 3–5 cm, complicating the placement of an infant straight Tenckhoff® catheter 30 or 31 cm long, with an intraperitoneal segment of 6–7 cm. In this setting, PD catheters are inserted percutaneously without tunneling under the skin, using a standard temporary PD catheter (7.5, 8.5, or 9 Fr, 8 cm length) or nontraditional catheters such as intravenous cannulas (22 or 24 gauge), central venous (14 gauge) or umbilical lines, angiocaths, and silicone wound drains. The lack of size-specific equipment for these patients and the use of improvised catheters are associated with PD malfunction due to leak and kinking [107].

Despite potential problems with access, PD is safe, simple, and inexpensive, thus representing the modality of choice for KRT in developing countries with limited resources. The main disadvantage of PD relative to extracorporeal blood purification therapies is the lower efficiency. HD and CKRT provide more rapid clearance of higher-molecular-weight solutes and faster fluid removal and are therefore superior for managing toxin removal, inborn errors of metabolism (IEM), and massive fluid overload (FO). Neonatal studies have reported a FO greater than 15–20% to be associated with poor outcomes including need for CKRT, prolonged NICU stay, time to extubation, or death within 30 days post-cardiothoracic surgery [108, 109]. In part because of these limitations in clearances and ultrafiltration, there has been some movement away from PD for the treatment of pediatric AKI in developed countries.

Hemodialysis

The use of intermittent HD for treating metabolic derangements in AKI or IEM is potentially associated with a superior solute clearance as compared with CKRT [110]. However, HD-associated hemodynamic instability and hypotension remain a significant problem for small patients. Animal data also suggest that high ammonia levels contribute to hypotension by up-regulating brain nitric oxide production that in turn suppresses the central sympathetic outflow causing systemic vasodilatation [111]. Given the strong limitations of HD due to its intermittent nature, complex application, high costs, and poor cardiovascular tolerance, the use of this technique in neonates with AKI has been supplanted by preference for CKRT.

Continuous Kidney Replacement Therapy

The use of CKRT in neonates was first described by Ronco in 1986 [112]. Four small newborns, ages 2–12 days, were treated with a modified continuous arteriovenous hemofiltration (CAVH) circuit. Blood lines were shortened to reduce the pressure drop, and a minifilter (0.005 m^2) was applied to optimize transmembrane pressure and ultrafiltration. Recently, the development of new machines for CKRT in neonates and small infants (either adapted or specifically conceived) has transformed infant extracorporeal blood purification from an orphan technology to an advanced care.

Technical challenges, including adequate vascular access, hypotension due to a relatively larger extracorporeal volume, and limited accuracy of fluid removal, have led to the preference of PD over CKRT in neonates with AKI. For example, a well-functioning vascular access using a central venous catheter can be difficult to obtain in very small infants, and the rates of both infectious and mechanical complications are exceedingly high. Access diameter significantly affects circuit survival. In the Prospective Pediatric CRRT (ppCRRT Registry) experience, none of the five French catheters used to provide CKRT in children with AKI lasted longer than 20 h [113]. Functional performances of catheters ranging from 7 to 9 French were better than with 5 Fr, with survival also favored by internal jugular vein insertion versus subclavian or femoral access. However, complications of catheterization are more common in babies because of the proportionally larger catheter caliber. Larger catheters relative to vessel size have the additional risk of causing central vessel stenosis, a complication that can impact the dialysis options of neonates and infants who will potentially have future KRT need. When using “standard” adult equipment with small central venous lines, access pressures surpass the machine operating limits with increased risk of alarms and shorter circuit lifespan. Machines designed specifically for small infants have overcome this problem by using a syringe-based system or miniaturized roller blood pumps. With appropriately sized equipment, single-lumen or small size dual-lumen catheters can be used in neonates to obtain adequate blood flows.

CKRT in neonates and infants requires a high precision of fluid balance and hemodynamic stability. In a case series of 174 children requiring CKRT, hypotension on connection was detected in 53 patients (30.4%) [114]. Extracorporeal circuit priming volume ideally should not exceed 10% of a patient’s circulating blood volume to avoid acute blood depletion with circuit initiation. When priming volume exceeds 10% of the patient’s circulating blood volume, a blood prime is strongly recommended to minimize hemodilution and hemodynamic instability. As an example, a 3 kg neonate requiring CKRT would have an overall blood volume of about 240 ml (80 ml/kg). Existing adult machines with pediatric set circuits have an extracorporeal prime volume in the range of 59–100 ml, thus exceeding the safe extracorporeal volume for neonates. This requires priming the circuits with blood, exposing the baby to potassium and citrate overload, transfusion reactions, infectious risk, and sensitization due to HLA exposure. Moreover, conventional HD and CKRT machines cannot control fluid balance better than ±30 ml/h and therefore are not approved for use with patients of low body weight (<8 kg).

Specialized Equipment

In 2005, Coulthard reported the results of an automated miniaturized syringe-driven machine to treat four babies weighing between 800 g and 3.4 kg, using a single-lumen access line, and without the need for blood-priming [115]. This device, the Newcastle Infant Dialysis and Ultrafiltration System (NIDUS®, Allmed, UK), is designed to provide single-lumen HD and ultrafiltration to children weighing between 800 g and 8 kg. A clinical study aimed at evaluating efficacy, safety, and outcomes of NIDUS machine as compared with the other existing KRT methods for babies <8 kg is currently active in UK.

In 2014, Ronco published the first-in-human use of a miniaturized Cardio-Renal Pediatric Dialysis Emergency Machine (CARPEDIEM®, Bellco-Medtronic, Mirandola, Italy) for treating a critically ill neonate weighing 2.9 kg with multiorgan failure and severe fluid overload [116, 117]. This device is a pump-driven machine that functions with a small double lumen catheter, and it is designed to provide multiple blood purification therapies to infants 2.5–10 kg including both pre- and postdilution CVVH as well as therapeutic plasma exchange and co-current CVVHD.

In 2016, Askenazi described the adaptation of an ultrafiltration device designed for fluid removal in adults with diuretic-resistant heart failure (Aquadex FlexFlow System®, CHF Solutions Inc., Eden Prairie, MN, USA) to provide a range of therapies, including CVVH, prolonged intermittent KRT, and slow continuous ultrafiltration, to children with AKI [118]. KRT with this device resulted in minimal complications in critically ill neonates and more than 50% of infants weighing <10 kg survived to come off KRT or transition to another modality of kidney support [119].

Novel technology specifically dedicated for neonates and small infants will further facilitate the application of CKRT in such patients. Operating characteristics of these machines are detailed in Table 5. The possibility to treat neonates with simplified and safe methods will likely induce care teams to apply extracorporeal blood purification earlier and for extended indications. CKRT can now be used in neonates not only in the case of extreme clinical conditions (i.e., rescue therapy for patients with severe fluid overload and peritoneal dialysis failure), but also for other indications requiring timely CKRT start, such as fluid balance control, hyperammonemia, drug intoxication, and short transient oliguric states with hypercatabolic complications.

Kidney Replacement Therapies in Inborn Errors of Metabolism

Inborn errors of metabolism (IEM) are a class of genetic disorders associated with failure of the metabolic pathways involved in either the breakdown or storage of carbohydrates, fatty acids, and proteins. Hyperammonemia (>100 umol/L or 170 ug/dL in neonates) is among the most important laboratory findings associated with IEM and is mainly due to urea cycle disorders or organic acidemias. This condition requires prompt recognition and aggressive therapy aimed at minimizing endogenous production and promoting removal of ammonia. The continued expansion of newborn screening allows for early identification and treatment, leading to reduced morbidity and mortality. However, early onset acute hyperammonemia can still present in neonates within the first few days of life after they start to feed, potentially resulting in acute encephalopathy. KRT are a cornerstone in the treatment of this condition, especially in those patients who have a rapid rise of serum ammonia levels (>500 μmol/l or 852 μg/dl) or fail to respond after 4 h of initial medical and nutritional management. Adverse prognostic factors include hyperammonemic coma lasting >3 days, increased intracranial pressure, and/or a plasma ammonia peak level >1.000 μmol/l (1.703 μg/dl) [120].

Intermittent HD and CKRT have proved more efficacious than PD in reducing ammonia levels. However, in an Italian multicenter study, delayed extracorporeal treatment was not superior to PD in improving the short-term outcome of neonates with hyperammonemia [121]. Predialysis ammonia levels, but not dialysis modality, were associated with death and neurologic sequelae. Thus, an aggressive and expeditious management of these patients is needed, one in which the choice of KRT modality should take into consideration the local resources, condition of the patient, serum ammonia levels trends, response to nitrogen-scavenger therapy, and patient's body weight. In general, PD should be performed in situations where extracorporeal therapies are not available or are unsafe, while extracorporeal therapies should be used in neonates who show a rapid rise in blood ammonia levels. Overall, with serum levels of ammonia in the range of 300–500 μmol/l (513–850 μg/dl) and while on scavenger treatment, the priority is providing the small patients with adequate dialysis access. Detailed

Table 5 Characteristics of extracorporeal dialysis machines specifically designed or adapted to treat neonates and small infants

Monitor	Modalities	Priming volume (ml)	Filter surface (m^2)	Membrane	Qb range (ml/min)	Qr or Qd range (ml/h)	UF rate range (ml/h)
NIDUS® (syringe-based system)	Single-lumen HD and ultrafiltration	5 + 4 to 10 ml of stroke volume	0.045	Polysulfone	Stroke volumes of 5 ml/kg up to 2 kg body weight, and then 10–12 ml	0–400	0–60 (±1)
CARPEDIEM®	CVVH CVVHD PEX	27 33 41	0.075 0.15 0.25	Polyethersulfone	2–50 (±1)	10–600	0–40 (±1)
Aquadex FlexFlow System® (adapted)	CVVH SCUF	33	0.12	Polysulfone	10–40 (±5)	External in-line medication infusion machine	0–500 (±10)

HD hemodialysis, *ml/kg* milliliters per kilogram, *ml* milliliter, *m* meters squared, *Qb* blood flow, *Qr* replacement fluid flow, *Qd* dialysate flow, *UF* ultrafiltration, *CVVH* continuous veno-venous hemofiltration, *CVVHD* continuous veno-venous hemodiafiltration, *PEX* plasma exchange, *SCUF* slow continuous ultrafiltration consensus guidelines for management of hyperammonemia in pediatric patients receiving CKRT have been published [122].
